(D ated: A pril 14, 2024)

We study the evolution of the single-hole spectral function when the ground state of the anisotropic-triangular-lattice antiferrom agnet changes from the incommensurate magnetically-ordered phase to the spin-liquid state. In order to describe both of the ground states on equal footing, we use the large-N approach where the transition between these two phases can be obtained by controlling the quantum uctuations via an 'e ective' spin magnitude. Adding a hole into these ground states is described by a t-J type model in the slave-ferm ion representation. Im - plications of our results to possible future ARPES experiments on insulating fustrated magnets, especially C s₂C uC l₄, are discussed.

I. IN TRODUCTION

The physics of geom etrically frustrated quantum m agnetic system s has been an arena for discovery of new and interesting phenom ena both on the theoretical and experimental fronts. Much of the e ort has been sparked by Anderson's proposal of the exotic resonating valence bond (RVB) spin-liquid phase^{1,2} and the belief that frustrated system s are likely to possess RVB spin-liquid-like ground states in two dimensions. Theoretical e orts in the past have explored a variety of two-dimensional frustrated system s^{3,4,5}. The discovery of superconductivity⁶ in Na_{0:35}CoO₂ 1.3HO has also raised the hope that the RVB could be the cause of superconductivity in certain frustrated m agnetic system s.

Recent theoretical works on the insulating anisotropictriangular-lattice antiferrom agnet^{7,8,9,10,11} have been particularly motivated by the experimental discovery of the fractionalized spin-liquid phase in C s₂C uC l₄^{12,13}, where spin-1/2 moments of C u antiferrom agnetically interact with each other in the layers of anisotropic triangular lattices. The experiment has shown that, with a su ciently high magnetic eld within its ordering plane, the compound looses its long-ranged cycloid order and enters the spin-liquid phase^{12,13}. In this phase, the dynam ical spin structure factor shows a broad pro le characteristic of fractionalization of spin-1 m agnons into a pair of spin-1/2 spinons^{12,13}.

A useful description of this transition can be obtained in the large-N approach^{8,14,15,16,17,18,19,20,21} to the antiferrom agnetic H eisenberg m odel on the anisotropic triangular lattice. Here the spin SU (2) symmetry is generalized to Sp(N) and the large-N limit of the m odel is investigated. In this approach, the quantum uctuations are controlled by the parameter that is the Sp(N) analog of the spin m agnitude. The resulting phase diagram contains both the incommensurate long-ranged order (LRO) phase²² (this corresponds to the cycloid order) and the spin-liquid state²³ in the large and sm all limits, respectively^{8,18}. Thus one m ay expect that 1= plays a role sim ilar to the in-plane magnetic eld in $C s_2 C u C l_4$. Indeed the spin structure factor of the spin-liquid state computed in the large-N theory^{9,10} boks very sim ilar to that observed in the neutron scattering experiments on $C s_2 C u C l_4^{12,13}$.

To this date, experim ental evidence of the RVB spinliquid phase in the anisotropic triangular lattice has been obtained only in neutron scattering experim ents on C s₂C uC $l_4^{12,13}$. Thus it is desirable to have independent experim entalcon rm ations of these results. O ne such experim ent m ay be the angle-resolved photoem ission spectroscopy (ARPES) that m easures the electron spectral function. In particular, the result of ARPES on an insulating com pound at half-lling corresponds to m easuring the single-hole spectral function in a given ground state of the insulator²⁴.

In this paper, we investigate the evolution of the singlehole spectral function across the transition between the incommensurate LRO phase and the spin-liquid phase. P reviously the single-hole spectral function in the LRO phase was investigated by taking into account the interaction of the hole with the spin waves 25,26,27,28. The well-de ned low-energy quasiparticle peak was found in these studies. This is due to the fact that small low energy density of states of the magnons leads to only a weak perturbation to the quasiparticle coherence at low energy. W hile this calculation is enough to describe the spectral function deep inside the ordered phase, an additional ingredient m ay have to be considered close to the transition toward the nearby spin-liquid state where the spinons are decon ned²³. The con nem ent of the spinons in the LRO phase is a low energy phenom enon and it is expected that the con nem ent energy scale will be very sm all near the transition. Therefore, it is expected that there will be spinon excitations at interm ediate to high energies near the transition and they may a ect the coherence of the hole motion. For example, the neutron scattering experim ents on the magnetically ordered phase of $C s_2 C u C l_4$ found the spinon continuum as well as the m agnon peak, im plying that this ordered phase is very

close to the transition $1^{2,13}$. Indeed the dom inant interaction near the transition m ay be the spinon-hole interaction since the m agnons are relatively suppressed close to the transition.

We use the results of the large-N theory to describe the transition between two ground states at half-lling. In this formulation, as will be explained later, the spinons appear at the mean eld level even in the LRO $phase^{8,14,\overline{15},16,17}$. Even though this is an artifact of the mean eld theory and the low energy spinons are conned due to the uctuation e ects beyond the mean eld theory^{14,15,16,17}, we can still use these spinons at interm ediate to high energies to m in ic the situations near the transition as described above. The motion of the singlehole is incorporated via a t-J type model in the slave ferm ion representation²⁷. Our computation takes into account the multiple interactions between the motion of the hole and the spin background, but does not include the vertex corrections. In principle, the latter approxim ation could lead to an underestim ation of the coherence in the motion of the hole. Comparison to the exact diagonalization study²⁹, however, suggests that the latter approximation does not change the overall structure of the spectral function in a signi cant fashion.

O ur results indicate that the single-hole spectral function still shows a well-de ned low-energy quasiparticle peak in the incommensurate LRO phase with a visible dispersion in momentum space. This is due to the fact that the density of states of spinons becomes smaller as the energy scale is decreased and, as a result, does not strongly disturb the low energy motion of the hole. As the transition to the spin-liquid state is approached, the spectral weight of the quasiparticle peak is decreased and the incoherent continuum at intermediate to high energies grows. Eventually the quasiparticle peak disappears at the transition. In the spin-liquid state, the single-hole spectral function only shows a broad incoherent continuum with little dispersion, which can be interpreted as a consequence of spin-charge separation.

The rest of the paper is organized as follows. In section II, we describe the form alism used to compute the single-hole spectral function and explain the approxim ation schemes used in this work. In section III, the num erical results on the single-hole spectral function in various phases are discussed. Finally, we sum marize our results and conclude in section IV.

II. FORM ULATION OF THE PROBLEM

At half-lling, the quantum ground states of the M ott insulator on the anisotropic triangular lattice are described by the H eisenberg m odel:

$$H_{J} = J_{1} \begin{array}{ccc} X & X \\ S_{i} & S_{i} + J_{2} \\ Ni; \\$$

where the rst and second terms represent the nearest and the next-nearest neighbour H eisenberg couplings, re-

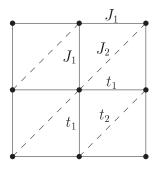

FIG.1: A nisotropic triangular lattice with two types of bond. The lattice is modelled by a square lattice with an additional interaction along one of the diagonals. The nearest neighbour coupling is associated with subscript 1 and the next-nearest neighbour coupling is associated with subscript 2.

spectively (see Fig.1). The motion of the single hole in a given ground state of the M ott insulator can be studied by adding the kinetic energy terms of the electrons;

$$H_{t} = \begin{array}{ccc} X & X & X \\ H_{t} = \begin{array}{ccc} t_{1} & (c_{1}^{y} c_{j} + h x;) & t_{2} & (c_{1}^{y} c_{j} + h x;); \\ & & & \\ & & & \\ & & & \\ & & & \\ & & & \\ \end{array}$$
(2)

where c_i^y is the creation operator of the electrons with spin = ";# (repeated indices are sum m ed) and it is assumed that there is no doubly occupied site in the H ilbert space to take into account the strong correlation inherent in the M ott insulator.

A . G round States of the M ott Insulator via the Large-N Sp(N) H eisenberg M odel

A useful form ulation of the Heisenberg model in Eq.1 can be obtained from a bosonic representation of the SU (2) spin via $S_i^a = \frac{1}{2}b_i^{y} \stackrel{a}{}_{0}b_i^{0}$, where a (a = x;y;z) are the Pauli matrices and b_i^{0} is the canonical bosonic operator. In addition, the constraint $b_i^{y} b_i^{0} = n_b = 2S$ must be imposed at each site, where S is the magnitude of the spin. In order to study this model on frustrated lattices in a controlled fashion and to obtain results that are non-perturbative in the coupling constants, we consider the Sp(N) generalization^{14,15,16,17} of the physical spin SU (2) ' Sp(1). This can be achieved by introducing N avours of bosons at each site, b_i^{1} , where = (n;) and n = 1;:::N is the avour index. Here again the boson num ber at each site, $n_b = b_i^{y} b_i^{1}$, must be xed. The resulting Sp(N) Heisenberg model is given by^{14,15,16,17}

$$H_{Sp(N)} = \sum_{i>j}^{X} \frac{J_{ij}}{2N} (J \quad b_{i}^{y} \quad b_{j}^{y}) (J \quad b_{i} \quad b_{j}); \quad (3)$$

where $J_{ij} = J_1$ and J_2 on the nearest and next-nearest neighbour links, respectively. Here J = J is a

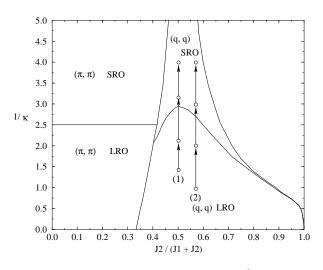

FIG.2: The zero tem perature phase diagram⁸ of the Sp(N) H eisenberg antiferrom agnet on the anisotropic triangular lattice at large N .1= represents the strength of quantum uctuations. Single hole spectral functions are evaluated at each of the ground states denoted by the circles along paths (1) and (2). See text for details.

We consider the large-N lim it of this model at a xed boson density per avour, $= n_b = N$. Notice that = 2Swhen N = 1. Thus is the Sp(N) analog of 2S and controls the strength of quantum uctuations. The large-N mean-eld theory of this model has been analyzed⁸ and the phase diagram at large-N has been obtained as a function of and $J_2 = (J_1 + J_2)$ (see Fig 2)⁸. For large values of , quantum uctuations are sm all so that the LRO states arise by breaking the globalSp (N) sym m etry. In the small lim it, strong quantum uctuations lead to param agnetic states with only short-ranged order (SRO). In the phase diagram of F ig 2, the ordering wavevector of the LRO states (and the corresponding SRO phases) are labeled by the ordering wavevector $q = (q_1; q_2)$ in two dimensions. It has been known that (;) SRO phase develops the valence-bond-solid order upon inclusion of singular uctuations beyond the mean-eld theory and the Berry phase $e ect^{4,8}$. In this paper, we will consider the transition between the incommensurate (q;q) LRO and the (q;q) SRO phases that respectively correspond to the cycloid-ordered and the translationally-invariant spin-liquid phases discovered in the experim ent involving $C s_2 C u C l_4^{12,13}$.

Now, for future reference, some explanation of the large-N mean-eld theory is in order. The presence of the LRO_p can be described by the condensation of bosons, $bb_i^n i = N_1^n x_i$, where the c-number eld x_i quanties the condensate. Thus, in the LRO phase, it is convenient

to parametrize the bosonic elds as

$$b_{i}^{n} = \begin{matrix} p \overline{N} x_{i} \\ b_{i}^{n} \end{matrix}; \qquad (4)$$

where m = 2;::::N. On the other hand, none of the bosons is condensed in the SRO phase. A fler decoupling the quartic boson interaction in Eq.3 by the Hubbard-Stratonovic eds Q_{ij}, the mean-edd Ham iltonian can be obtained as^{14,15,16,17,18}

$$H_{MF} = \frac{X}{i^{5}j} \frac{N}{2} J_{ij}Q_{ij}$$

$$= \frac{\frac{0}{2} J_{ij}Q_{ij} N x_{i}x_{j}^{0} + \frac{X^{N}}{m} b_{j}^{m} b_{j}^{m} + hc;$$

$$= \frac{X}{i} N \dot{x}_{i} \dot{y}_{j}^{2} + \frac{X^{N}}{b_{im}^{y}} b_{i}^{m} n_{b};$$
(5)

where $Q_{ij} = \frac{1}{N}hJ$ $b_i^y b_j^y$ i at the saddle of the corresponding action. Here the last term of Eq.5 takes care of the constraint on the boson number at each site and i is the Lagrange multiplier.

At the m ean- eld level, $Q_{ij} = Q_1$ and Q_2 on the nearest and the next-nearest neighbour links, and is a siteindependent constant. In the LRO phase, the boson condensate fraction has the form

$$\mathbf{x}_{i"} = \mathbf{x} e^{i\mathbf{Q} \ \mathbf{r}_{i}}; \ \mathbf{x}_{i\#} = i\mathbf{x} \ e^{i\mathbf{Q} \ \mathbf{r}_{i}}; \tag{6}$$

where q = 2Q is the magnetic ordering wavevector. In the mean-eld theory, $Q_1; Q_2; x;$ and Q have to be determ ined self-consistently for a given $= n_b = N$.

The part of the Hamiltonian for the uncondensed bosons or spinons, b_{im} (m = 2; :::;N), can be diagonalized using the Bogoliubov transform ation:

$$H_{MF}^{0} = \begin{array}{c} X & X^{N} & & \\ &$$

where

The Bogoliubov quasiparticle operators, $_{\rm km}$ and $_{\rm km}$, are given by

$$\sum_{km}^{km} = \frac{u_{k} v_{k}}{v_{k} u_{k}} \frac{b_{km}}{b_{km}^{y}}; \qquad (9)$$

where

$$u_k = \frac{1}{p_{\overline{2}}} \frac{r}{k} + 1; \quad v_k = \frac{e^{i_k} r}{p_{\overline{2}}} \frac{r}{k} - 1:$$
 (10)

Notice that, in the SRO phase, there are no condensed bosons and all the spinons are described by Eq.7.

It has been known that the presence of uncon ned spinons is an artifact of the large-N mean-eld theory and these spinons are, in principle, con ned at low energies due to uctuations beyond the mean-eld theory^{14,15,16,17} Thus the spinons cannot be seen deep inside the LRO phases. The con nem ent scale below which the con nem ent occurs, how ever, can be very sm all when the transition to the spin-liquid phase is approached. Thus we expect that there exist 'almost'-decon ned (or loosely-con ned) spinons at interm ediate to high energy scales near the transition. At the transition point, this energy scale should be zero because the spinons are decon ned in the spin-liquid phase. In fact, the experiment on $C s_2 C u C l_4$ reveals the existence of both of the m agnon peak and the spinon continuum in the cycloidordered phase, indicating that this system is very close to the transition tow ard the spin-liquid ${\tt phase}^{12,13}$. W hile the con nem ent phenom enon cannot be captured by the m ean-eld theory, the existence of the decon ned spinons at the mean-eld level can be used to phenom enologically describe the existence of 'alm ost'-decon ned spinons near the transition. From now on, we will adopt this picture and exam ine the e ect of the 'alm ost'-decon ned spinons on the motion of the holes.

B. M otion of Single H ole and the Spectral Function

In order to describe the motion of a single hole in the large-N limit, we use the slave-ferm ion representation of the electron operator with the avour index:

$$c_{i:n}^{y} = f_{i} b_{i:n}^{y} ; \qquad (11)$$

where f_i represents the ferm ionic charge degree of freedom and $b_{i;n}\,$ the bosonic spin degree of freedom of the electrons.

The single-hole spectral function can be computed from the single-hole G reen's function:

$$G_{h}; (r;) = \frac{1}{N} \sum_{n=1}^{N} G_{h;n} (r;)$$
$$= \frac{1}{N} \sum_{n=1}^{N} H c_{n}^{y} (r;)c_{n} (0;0)i; (12)$$

where T is the time-ordering operator of the imaginary time. Notice that the physical hole G reen's-function is dened as the average of the G reen's functions in dierent avour channels. Since no avour degree of freedom is special on physical grounds, this is a legitim ate de nition of the hole G reen's function that turns out to be particularly useful for our purposes.

A fler analytic continuation, the spectral function can be obtained from

$$A_{h}$$
; $(k;!) = \frac{1}{-1} \text{Im} [G_{h}; (k;!+i)];$ (13)

where G_{h} ; (k;!) is the single-hole G reen's function in Fourier space.

At the mean-eld level, the single-hole G reen's function can be written as

$$G_{h}$$
; (r;) $\frac{1}{N} \sum_{n}^{X} G_{f}$ (r;) $G_{b;n}$ (r;); (14)

where

$$G_{f}(r;) = hT f(r;)f^{y}(0;0)i$$

$$G_{b;n}(r;) = hT b_{n}^{y}(r;)b_{n}(0;0)i; (15)$$

In Fourier space, we get

$$G_{h;}(k;!) = \frac{1}{N} \frac{X X Z}{n q} d G_{b;n}(k q;!) G_{f}(q;): (16)$$

Thus the single-hole G reen's function is given by the convolution of the ferm ionic and the bosonic G reen's functions.

In this work, we will assume that the injection of the single-hole does not a ect the underlying ground state at half-lling. In this case, it may be su cient to use the bare bosonic G reen's-function, $G_{b;n}^0$, in the absence of the hole²⁷. On the other hand, the ferm ionic degree of freedom of the hole will be very much a ected by the presence of the excitations in the underlying ground state. We will compute the renormalized ferm ionic G reen's function using the self-consistent D yson equation^{27,28}, where the non-crossing diagram s are summed. Possible e ect of the vertex corrections in the ferm ionic G reen's function and Eq.14 will be discussed later.

1. Computation of the Ferm ion Green's Function

The proper large-N generalization of the kinetic energy term s of the holes in Eq.2 is given by

$$H_{t} = \frac{t_{i}}{N} \frac{X}{(f_{i}b_{i;n}^{y} \ b_{j;n} \ f_{j}^{y} + h::)}$$

$$\frac{t_{2}}{N} \frac{X}{(f_{i}b_{i;n}^{y} \ b_{j;n} \ f_{j}^{y} + h::)}$$

$$(17)$$

Fourier transform ation of these terms leads to

$$H_{t} = \frac{1}{N} \sum_{k \neq 0}^{X} f_{k} b_{k}^{y} f_{m} b_{k} f_{m} f_{k}^{y} f_{k}^{y} f_{m}$$
(18)

where

$$k = 2 [t_1 (\cos k_x + \cos k_y) + t_2 \cos (k_x + k_y)]:$$
 (19)

These hopping terms give rise to the interaction between the hole and the spin background.

In the LRO phase, the existence of the condensed bosons, $jb_{k,n}$ $if = N \frac{n}{1}jxf_{k,2}$, leads to

$$H_{t} = 2 \sum_{k=0}^{X} f_{k}^{y} f_{k}^{y} f_{k}$$

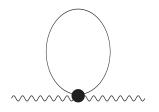

FIG. 3: The self-energy correction of Eq 21. The wavy line represents the ferm ionic propagator and the solid line represents the bosonic propagator.

+
$$\frac{1}{N} \frac{X \quad X^{N}}{\sum_{k \in {}^{0}\mathrm{G} m = 2}} b_{k} \circ b_{k}^{y} \circ b_{k} \circ g_{m} f_{k}^{y} f_{k} g$$
 (20)

The second term corresponds to the interaction between the uncondensed spinons and the ferm ion and gives rise to the ferm ion self-energy corrections.

Let us not consider the perturbative self-energy corrections in $t_1=N$ and $t_2=N$. The lowest-order correction is given by (see Fig.3)

$${}_{1}(k) = 2 \sum_{k^{0}}^{X} {}_{k \ k} \circ j y_{k} \circ j^{2}; \qquad (21)$$

where (N = 1) = N = 1 is used. The next order correction involves the diagram in Fig.4 and can be computed as

where

$$f_{k\,k^{\,0}q} = j_{k\ k} \circ u_{k} \circ v_{k^{\,0}\ q} + {}_{k+k^{\,0}\ q} u_{k^{\,0}\ q} v_{k^{\,0}} \int_{2}^{2}$$
(23)

and $(N = 1)=N^2$ 1=N is used. Notice that, in the perturbative calculation, the bare ferm ionic G reen's-function, G_f^0 , should be used for G_f in Eq.22.

In order to take into account the multiple interactions, however, we need to go beyond the perturbative evaluations of the self-energy contributions. In our work, we will determ ine the renorm alized ferm ion G reen's function, G_f , by summing up diagrams in the non-crossing approximation. This amounts to using the renorm alized G reen's function in Eq.22 and solving the following D yson equation for the ferm ion G reen's function.

$$G_{f}^{1}(k;!) = ! + 2j_{k}j_{kQ}^{2}$$
 (k;!): (24)

In the numerical solution of this equation, we set the coe cient of the self-energy correction in Eq.22 to be one for convenience (i.e. 1=N = 1). Notice that $2j_k j_{k=0}^2$

1 (k) corresponds to the dynam ically generated 'band' dispersion for the ferm ions at the lowest order. In the case of the SRO phase, the same D yson equation can be used with x = 0 in Eq.24.

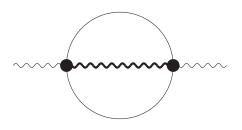

FIG.4: The self-energy correction of Eq.22. The thick wavy line is the exact ferm ionic propagator. Combined with the contribution from Fig.3, this gives rise to the D yson equation for the ferm ionic propagator in Eq.24.

2. Evaluation of the Single-Hole Spectral Function

In the LRO phase, the G reen's function for the condensed bosons in the Fourier space is given by

$$G_{b;1"}(k;!) = N \dot{x} \dot{f}_{k;Q} (!)$$

$$G_{b;1\#}(k;!) = N \dot{x} \dot{f}_{k;Q} (!): (25)$$

On the other hand, the G reen's function for the uncondensed bosons are obtained as (for both = ";#)

$$G_{bm} (k; ! + i) = \frac{j y_k f}{(! + i)} \frac{u_k^2}{(! + k + i)} (26)$$

Then the single-hole G reen's function in Eq.16 can be written as

$$G_{h;} = G_{h;1} + \frac{N-1}{N}G_{h;2} \quad G_{h;1} + G_{h;2} : (27)$$

The single-hole spectral function, A_{h} ; = (1=) Im G_h; is now given by

$$A_{h;}$$
 (k;!) = $A_{h;1}$ (k;!) + $A_{h;2}$ (k;!): (28)

The rst contribution from the condensed bosons is

$$A_{h;1"}(k;!) = \frac{1}{2} jx j^{2} \text{Im} G_{f}(k + Q;! + i);$$

$$A_{h;1\#}(k;!) = \frac{1}{2} jx j^{2} \text{Im} G_{f}(k - Q;! + i): (29)$$

The second term is due to the interaction between the ferm ion and the uncondensed bosons and is given by

$$A_{h;2} X_{X}^{(k; \frac{1}{Z})} = dy A_{f} (q; y) A_{b;2} (q k; y !) (! > 0)$$

$$= X_{q}^{(q; y)} A_{f} (q; y) A_{b;2} (q k; y !) (! < 0); (30)$$

where $A_f = (1 =) \text{Im } G_f$ and $A_{b;2} = (1 =) \text{Im } G_{b;2}$. On the other hand, in the spin-liquid state (or the SRO phase), the rst term in Eq.28 vanishes because there is

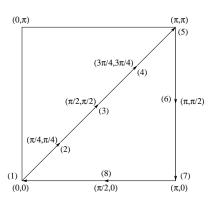

FIG.5: Eight momenta in the principal Brillouin zone at which the spectral functions are evaluated.

no boson condensate and the spectral function is entirely given by the second term .

W e will rst numerically solve the Dyson equation for the ferm ion G reen's function in both the LRO and the spin-liquid phases. Then the ferm ion spectral function can be convoluted with the boson spectral functions in the two phases to get the expression for the single-hole spectral function. The evolution of the resulting singlehole spectral function across the transition between the LRO and the spin-liquid phases is discussed in the next section.

III. NUMERICAL RESULTS

At rst, the ferm ion G reen's function is obtained by solving numerically the self-consistent D yson equation on a discrete m esh of k and ! points. In order to do so, we have solved the saddle point equation of the large-N m ean - eld theory for each set of $;J_1;J_2$, and use the m ean eld results as the input to the D yson equation of the ferm ion G reen's function. The full hole G reen's-function is then computed by using Eqs.28,29,30. The calculations are done with a nite lattice of size 8^2 . We have con rm ed that the overall structure of the spectral function does not change when the size of the system is increased to 16^2 .

The evolution of the spectral function near the transition between the incommensurate LRO and the spinliquid phases, is examined at 8 di erent points in the phase diagram by following two di erent paths (see Fig.2). On both paths, the transition between two states is achieved by changing for a given $J_2 = (J_1 + J_2)$. For each ground state, the spectral function is calculated at eight di erent momenta in the principal B rillouin zone. These eightmomenta are shown in Fig.5. When the spectral functions are plotted for these eight momenta, they will be arranged from bottom up in the order indicated by the bracketed numbers as shown in Fig.6. All other similar plots will follow the same convention.

A sexplained earlier, quantum uctuations are stronger

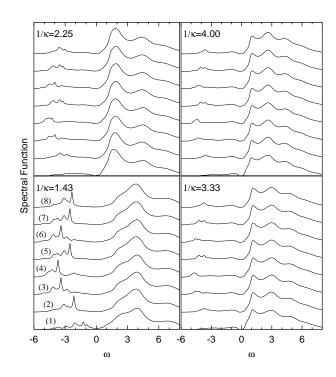

FIG.6: Evolution of the spectral functions along path 1 in Fig. 2. $J_1 = J_2 = 1.0$ and $t_1=J_1 = t_2=J_2 = 2.5$.

for smaller values of . Thus, the transition from the incommensurate LRO phase to the spin-liquid state can be obtained by decreasing for a given value of $J_2 = (J_1 + J_2)$. We consider paths (1) and (2) corresponding to $J_1=J_2 = 1$ and $J_1=J_2 = 0.75$, respectively. The results for the four di erent values of are shown in Fig.6 for path (1) and in Fig.7 for path (2).

The results of paths (1) and (2) are very similar. At large , there exists a sharp low energy peak in the incommensurate LRO phase suggesting the existence of a coherent hole excitation or a quasiparticle. Notice that the incoherent continuum at higher energies are due to the existence of the 'uncon ned' spinons. In the spinliquid phase, the quasiparticle peak completely disappears and only the incoherent broad continuum can be seen in the spectral function.

Notice that the spectral weight of the quasiparticle peak in the LRO phase decreases as the transition to the spin-liquid phase is approached and instead the spectral weight of the incoherent continuum grows. This is due to the fact that the spectral weight of the quasiparticle peak is proportional to the strength of the boson condensate or the magnetic order parameter that decreases as the transition point is approached. This can be observed in both Fig.6 and Fig.7, but is illustrated more clearly in the latter gure. In Fig.7, the strong quasiparticle peak seen when = 1 diminishes as we approach the transition. The remnant of the peak is indicated by the arrows in the gure. Upon careful inspection, a slightly broad bump beside the peak consistently persists in all of the

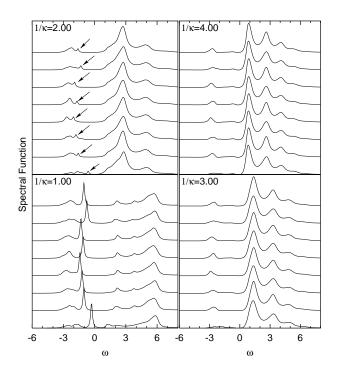

FIG.7: Evolution of the spectral functions along path 2 in Fig. 2. $J_1 = 0.75$; $J_2 = 1.0$ and $t_1=J_1 = t_2=J_2 = 2.5$.

plots indicating that it is a contribution from the unconned spinons. One can observe in both gures that as the spectral weight of the quasiparticle peak shrinks, the rem aining spectral weight gradually moves to the 'unconned' spinons at higher energies.

The incoherent continuum in the SRO phase arises because the injected hole decays into its charge and spin degrees of freedom and they do not propagate together in a coherent fashion. The origin of the broad continuum in the LRO phase is basically the same; the 'uncon ned' spinons make the motion of the hole incoherent. The reason why the low energy quasiparticle peak survives in the LRO phase is that the density of states of the spinons becom es very small in the low energy limit so that the spin degree of freedom of the injected hole at low energy cannot e ciently decay into the spinon continuum.

W e have also con med that varying the hopping am plitude, t, does not change the qualitative behaviour of the spectral function. The only change is that the bandwidth of the quasiparticle is increased as the hopping am plitude becom es bigger.

IV. SUMMARY AND CONCLUSION

We investigated the single-hole spectral function in the anisotropic-triangular-lattice Heisenberg antiferromagnet. In particular, we studied the evolution of the single-hole spectral function across the transition between the incommensurate LRO phase and the spinliquid state. This phase transition can be described by the large-N Sp(N) mean-eld theory 14,15,16,17,18 , where the Sp(N) analog of the spin magnitude, , can be adjusted to control the strength of quantum uctuations. The motion of the single hole injected into the insulator is studied via the t-J typem odel in the slave ferm ion representation, where the electron is represented as the com posite of a charge-carrying ferm ion and a spin-carrying boson. Taking into account the multiple interactions between the injected hole and the excitations of the underlying insulator in the non-crossing approximation, we evaluated the single-hole spectral function in both of the LRO and the spin-liquid phases.

It is found that, in the LRO phase, the quasiparticle peak exists at low energy and the broad incoherent background also arises at interm ediate to high energies. This incoherent continuum arises due to the existence of 'uncon ned'spinons in the large-N mean-eld theory. In principle, these spinons should be con ned below a 'connem ent'energy scale due to a uctuation e ect beyond the m ean-eld theory 4 . N ear the transition, how ever, the con nem ent energy scale becom es very sm all (in fact it is zero at the transition) so that the spinons at interm ediate to high energies are 'alm ost' uncon ned. In this respect, our calculation is particularly suited to describe the spectral function near the transition. As the transition to the spin-liquid state is approached, the spectral weight of the quasiparticle peak goes to zero and the incoherent continuum grows. Finally, in the spin-liquid phase, only the incoherent continuum survives in the spectral function. This is due to the fact that the injected hole can decay into the charge-carrying ferm ionic excitation and the spin-carrying spinon and the motions of these excitations are not coherent together.

In our studies, we neglected various vertex corrections, which m ay have lead to an underestimation of the coherence, especially in the spin-liquid phase. However, the recent exact diagonalization study of the spin-liquid state on the K agom e lattice showed spectral functions that were indeed completely incoherent²⁹, leading to the conclusion that the vertex correction would not change the qualitative behaviours obtained in our study.

Our work is relevant to possible ARPES experiments on M ott insulators on the anisotropic triangular lattice since the ARPES on the insulator can measure the singlehole spectral function²⁴. In particular, notice that the neutron scattering experiment on Cs2CuCl4 reveals the existence of the spinon continuum at interm ediate to high energies in the LRO phase near the transition as well as in the spin-liquid phase^{12,13}. The parameter 1 = in the large-N theory plays the same role as the in-plane m agnetic eld in the experiment on Cs_2CuCl_4 , where the transition between the two phases is achieved by changing the in-plane eld or temperature. Thus we expect that, in light of our work, the ARPES experiments on such systems will provide independent con mation of the spinon continuum discovered in the neutron scattering experiments on $C s_2 C u C l_4$ or in related system s.
