We study a spin orbital model in which the spin-spin interaction couples linearly to the orbital isospin. Fluctuations drive the transition from paramagnetic state to C type ordered state into a strongly rst order one, as observed in V_2O_3 . At T = 0, there is a ferro-orbital-C-spin to ferro-orbital-G-spin transition. C base to the transition point, the system shows dynamically generated dimension reduction and crossover, resulting in one or more spin reentrant transitions.

Recently there has been growing interest in the e ects of orbital degeneracy on the physics of transition m etal oxides. The e ective spin Ham iltonian of the insulating phase of such systems may depend crucially on orbital short-ranged and long-ranged correlations. As a result, m agnetic ordering can becom e anom alous orm ay even be suppressed altogether. At the sam e time, orbital physics is also a ected by spin uctuations and correlations. The interplay between spin and orbital degrees of freedom is fundam ental to much of the physics of transition m etal oxides [1, 2]. In this paper we investigate certain aspects of this interplay, emphasizing on the e ects of therm al and quantum spin uctuations on orbital ordering and the e ects of orbital ordering on spin physics. Our most interesting result is that the system can exhibit dim ension reduction and dimension crossover of spin physics as a function of tem perature due to orbital ordering.

In the insulating phase of transition m etal oxides, the dom inating energy scales for the transition m etal ions are the on-site C oulomb repulsion, H und's rule coupling, and the crystal eld due to the surrounding oxygen ions. Neglecting weak spin-orbit e ect, the general spin H am iltonian with two-fold degenerate orbitals (represented by pseudospin = 1=2) is of the form [3], H = $_{\rm hiji} (J_{ij}S_i \ S + K_{ij})$, where J_{ij} and K_{ij} are functions of $_i$, and $_j$. This H am iltonian has global SU (2) invariance in spin space and a lower and discrete rotational symmetry in space [4, 5, 6, 7, 8]. Out of the general class of such H am iltonians, we will focus on those on a cubic lattice of the form

$$H = J_0 \qquad S_i \qquad$$

Here the unit vectors $\mathbf{b}_{1j} = \mathbf{b}_1$; \mathbf{b}_2 ; \mathbf{b}_3 for i; j nearest neighbor in the x; y; z directions respectively. In this model, the interplay between spins and orbitals arises from the second term which is linear in . This linear term will be present provided the two eigenvalues of the hopping matrix are di erent, while the \mathbf{b}_1 's will depend on how the two degenerate orbitals transform under lattice rotations. For speci city, we take the \mathbf{b}_1 's to be unit vectors in the x z plane, with $\mathbf{b}_3 = \mathbf{b}$; while \mathbf{b}_1

and \mathbf{b}_2 are rotated from \mathbf{b}_3 by 120^0 and 240^0 : M ore generally, there are also quadratic in terms, which we assum e to be weak com pared to the two term s kept. This implies that any orbital ordering in the system will be due to spin-orbital coupling rather than Jahn-Teller effect. A ssum ing this is the case, and with the choice of **b**_i 's above, this spin-orbital H am iltonian can serve as a model for one electron or hole per site in the doubly degenerate e_{q} levels of cubic peroskites [4] as well as a possible model for V_2O_3 [9]. For the latter, each site on the cubic lattice is the topological equivalence of a vertical pair of sites on the corundum lattice of V203. The coupling J₀ depends strongly on and decreases with the Hund's coupling, while K is only weakly dependent on it. We consider $J_0 > 0$, and with an appropriate de nition of , we also have K > 0. The calculation shown here will be for S = 2, the value of S for the V_2O_3 bond m odel, but the results are qualitatively the sam e for other S. The results are also applicable to other lattices and other choices of the b_i's.

W hile J₀ favors conventional (G-type) AF magnetic correlations so that nearest neighbor spins are allAF correlated, K favors, along with orbital ordering, anom alous m agnetic correlations break the cubic lattice rotational sym m etry, for exam ple C -type ordering with AF correlation in ab plane and FM correlation in c direction. In this paper, we investigate the phase diagram of this model in the temperature T and $J_0=K$ plane. Our main results are: 1) At low T; orbital ordering gives rise to e ective dimension reduction of the spin physics for $J_0=K$ close to 2:2) The weakening of orbital ordering with increasing T can lead to dimension crossover from 2D to 3D and vice versa. 3) The dimension crossover e ect together with thermal uctuation e ects on the spins can lead to an order by disorder mechanism and one or more reentrant transitions. 4) The strongly rst order nature of the magnetic transition in V_2O_3 is explained [10]. The underlying physics behind these results are orbital ordering coupled with spin short-ranged correlations and quantum uctuations.

W ithin the context of the bond m odel for V_2O_3 ; our m odelhasbeen studied by Joshiet. al. using a single-site

m ean eld theory. In order to include short range spin correlation and quantum uctuations, we use a m odi ed m ean eld approach to decouple the spin orbital H am iltonian. W e begin with the Feynm an-H ellm an theorem [11]:

$$F F_0 + hH H_0 i_0$$
(2)

Here F is the true free energy of the system and H is the actual Ham iltonian given in Eq. 1. H_0 is a variational Ham iltonian and hi_0 is the therm al expectation value with respect to H_0 . F_0 is the free energy of the system with Ham iltonian H_0 . We take our variational Ham iltonian as,

$$H_{0} = H_{S} + H$$
(3)

$$H_{S} = J_{?} \qquad S_{i} \qquad S_{i} + J_{k} \qquad S_{i} \qquad S_{i} \qquad S_{i} \qquad M_{iji} \qquad M_{iji} \qquad M_{iz} \qquad$$

where, $J_2 = J_0 = 2Kt$, and $J_k = J_0 + Kt$, with t 0. In H_S above, the rst sum is for nearest neighbor pairs along the z direction and the second sum is for pairs on the same xy plane. t and A are variational parameters. O ur choice of H₀ is based on the expectation that orbital ordering will be ferro-orbital.

M inimization of Feynman-Hellman free energy with respect to the variational parameters gives two self consistent equations, A = B and $t = h_z i = \tanh(2K A)$. $B = B_2$, B_k , with $B_2 = hS_i$, Si_z and $B_k = hS_i$, Si_{xyy} as out of plane and in-plane nearest neighbor spin spin correlation obtained from H_S.

Note that while non zero value of t signi es long range orbital order, non zero value of B only signi es short range spin correlations. If $B_2 \notin B_k$; spin correlations will be di erent from isotropic G type antiferrom agnet. In particular, if $B_k < 0$; and $B_2 > 0$; that would correspond to C type m agnetic correlations. Our decoupling schem e allow sus to study the e ects of short-ranged spinspin correlations, but not short-ranged orbital correlations. However, we expect spin uctuations to be dom inant because of its continuous symmetry. Joint spinorbital correlations are also ignored, but we expect these to be weak com pared to spin uctuations far away from the SU (4) lim it [12].

Note that $J_k > 0$, but J_2 can be either positive or negative in H_S , depending on the value of orbital order parameter t. H_S is an Heisenberg Ham iltonian with spatial anisotropy. In order to include short-ranged correlations and quantum uctuations, we use renorm alized spin wave theory (RSW T) [13, 14, 15], which unlike traditional spin wave theory (SW T) is applicable to both m agnetically ordered and disordered phase. For the Heisenberg antiferrom agnet on the square lattice, H irsch and Tang [14] have shown that this method can provide quantitatively accurate results. In RSW T, m agnonm agnon interactions are approxim ated by introducing a constraint that the total staggered m agnetization be zero; $M = \sum_{i2A} S_i^z \qquad _{j2B} S_j^z = 0, \text{ or equivalently that the}$ average number of spin waves per site is S. This constraint can be implemented by introducing into H_S a Lagrange multiplier :

$$H_{S} = J_{?} \begin{array}{ccc} X^{z} & X^{z} \\ S_{i} & S_{j} + J_{k} \\ & & S_{i} \end{array} \begin{array}{ccc} X^{z} & X^{z} \\ S_{i} & S_{j} \end{array} M \qquad (4)$$

The modi ed H $_{\rm S}\,$ (Eq. 4) is then solved using usual spin wave theory by expanding to quadratic order in H olstein-P rim ako bosons.

C lassically, the spins will order as C -type and G -type for the $J_2 < 0$ and $J_2 > 0$ cases respectively. Thus, the sublattice designation will di er in the two cases and the spin wave calculation must be done separately. Let us de ne Q = $\frac{J_2}{J_k}$ and $!_k$ and $!_k$, magnon energies for Q > 0 and Q < 0 cases respectively. We see that Q is a dimensionless measure of the elective spin-spin coupling anisotropy. Note that 2 < Q < 1. The chemical potential is obtained from the constraint equation,

$$S + \frac{1}{2} = \frac{Z}{(2)^{d}} \frac{d^{d} \tilde{k}}{(2)^{d}} \frac{1}{e^{\frac{1}{k}} - 1} + \frac{1}{2} F (;k); \quad (5)$$

where is the inverse temperature and $!_k$ are given $q = \frac{by}{k}, \frac{!_k^+}{k} = \frac{6J_kS}{2} \frac{p}{k^2}$ and $!_k = \frac{6J_kS}{k} \frac{p}{2} \frac{p}{k^2}$ and $!_k = \frac{6J_kS}{k} \frac{p}{2} \frac{p}{k^2}$ with elective magnon chemical potential, $= \frac{1}{3}(2 + \frac{1}{2}p + \frac{1}{4SJ_k})$. $_k = \frac{1}{3}(\cos k_x + \cos k_y + Q \cos k_z)$, $_{k?} = \cos k_z$ and $_{kk} = \frac{1}{2}(\cos k_x + \cos k_y)$. $F_+(;k) = (2 - \frac{2}{k})^{1=2}$ and $F_-(;k) = (+\frac{Q}{3} \frac{1}{k?})((+\frac{Q}{3} \frac{1}{k?})^2 (\frac{2}{3} \frac{1}{kk})^2)^{1=2}$ should be used for Q > 0; < 0 respectively.

A fter solving for , B can be calculated, and the self consistent equation for t can be solved using iterative scheme. W hen there are more than one solutions for t; we compare their free energies to choose the stable solution for each temperature. One anomaly of the RSW T approach is that $B_{?}$ and B_{k} need to be calculated to one order of 1=S higher than the free energy to ensure the correct sign for spin correlation at high temperatures[13, 16]. This di erence is not signi cant for the self-consistent solutions close to and below the temperature of the rst phase transition in our model.

In FIG. 3, we show the resulting phase diagram for the case of S = 2; the value of S for the V_2O_3 bond model. In what follows, P stands for para (i.e. disordered), F stands for ferro ordering, C stands for C type ordering, G stands for G-type ordering, and O and S refer to orbital and spin respectively. Five phases are possible in the model. These phases are POPS, FOCS, FOPS (m ay be GS or CS short-ranged correlations), POGS (isotropic AFLRO), FOGS (anisotropic AFLRO). The phase consistent with the magnetic and orbital ordering observed in V_2O_3 is the FOCS phase [9, 10, 17, 18]. The phase transitions the system undergoes as the tem perature is lowered depend on the parameter J_0 =K and can be grouped into 6 regimes discussed below. In all cases, the orbital transition is rst order while the spin transitions are second order unless accompanied by the orbital transition.

FIG.1: (a) Phase diagram of spin-2 doubly degenerated spin orbital model. (b) B low up of the region close to $J_0=K = 2$: Regimes III, IV, and V described in the text correspond to values of $J_0=K$ between AB, BC, and CD respectively. D otted line gives T_2 ; the dimension reduction tem perature. To its left (right), the spin coupling anisotropy parameter Q < 0 (> 0).

J₀ K For regime I (0 0:506), the regime relevant for V_2O_3 ; the transition is a direct one from the disordered phase into the FOCS phase with both spins and orbitals ordered. Experim ents showed this transition to be strongly rst order. W hile single site mean eld theory (SSM FT) for our Ham iltonian is able to obtain a rst order transition in this parameter regime, it was only weakly rst order. By including short-ranged correlations in the present theory, the POPS phase is stabilized, and the rst order nature of the transition is signi cantly enhanced. Entropy jump calculated from the free energy derivative, is larger than $1k_B$ per site throughout regime I, with e.g. a value of $1.28k_B$ for $J_0=K = 0.25$, which com pares favorably with the experim ental value of $1.4k_B$ (each site on the bond model corresponds to a pair of V ions). We should note that the mechanism for large entropy jump here is quite di erent from the usual uc-

tuation driven st order transition where the dom inant uctuations are from modes close to the mean eld free energy m in im um . For this system , how ever, the dom inant uctuations are G-type magnetic ones, and very far from the C-type magnetic ordering. A nother issue in V₂O₃ is why spins and orbitals order at the sam e tem perature. In principle, it is possible to have a spin Peierls transition driven by FO ordering instead of a FOCS transition [6]. This issue cannot be addressed by SSM FT, but can be using our modi ed MFT, which shows that for $J_0=K$ appropriate for V_2O_3 ; there is no FO driven spin Peierls phase. However, we will see below that such a phase can indeed occur in other param eter regim es of ourm odel, but it will necessarily be preceded by a POGS ordering at higher tem perature. Thus, a phenom enological explanation of the concurrence of orbital and CS ordering in V_2O_3 is that there is no GS ordering at a higher tem perature.

Regines II and VI (0:506 < $\frac{J_0}{K}$ 1:976 and 2:013 < $\frac{J_0}{K}$ respectively) show two phase transitions. The system rst undergoes an isotropic (Q = 1) POGS ordering. Then at a lower temperature, the spin-orbital coupling causes a rst order FO transition that converts the spin ordering to CS (Q < 0) in regine EII and aniostropic GS (Q > 0; $\frac{6}{1}$ 1) in regines VI. Rather more interesting, how ever, are regines III, IV, and V, corresponding to 1:976 < $\frac{J_0}{K}$ 1:987, 1:987 < $\frac{J_0}{K}$ 2, and 2 < $\frac{J_0}{K}$ 2:013 respectively. These regines show multiple transitions, including reentrance. These transitions are consequences of e ective dimension reduction and dimension crossover in spin physics caused by orbital ordering.

To see this, let us rst consider T = 0; where within our MFT the orbital is always fully ordered. As a result, the e ective spin Hamiltonian from our decoupling scheme param eterized by Q changes continuously to sm aller posit ive Q and then eventually to negative Q as $J_0=K$ is decreased. At $J_0 = K = 2; Q = 0$ and the spins on di erent planes become decoupled, i.e. the spin Ham iltonian is that of a 2D Heisenberg antiferrom agnet. This is the orbitaldriven dimension reduction e ect at T = 0:Currentwisdom is that the ground state of the 2D H eisenberg anit ferrom agnetic H am iltonian is ordered at T = 0 in 2D even for S = 1=2: Thus there is spin LRO (anisotropic GS or CS) for all values of $J_0 = K$ at T = 0: At nite tem perature, therm al uctuations will weaken both the spin ordering and the orbital ordering, with the latter giving rise to e ective tem perature-dependent spin H am iltonian. The spin physics is best understood by considering how Q (t) changes with T together with the dependence of the spin transition tem perature $T_c (Q)$ on Q: For sm all ⊉ j:RSW T gives = 1=2. Because orτΩj;T_c(Q) bital has a discrete sym m etry, its order param eter t, and hence Q changes exponentially slow ly at low T; and the physics is dom inated by therm ald isordering of the spin. At higher T; the reduction in t becom es signi cant, and the corresponding change in Q can give rise to dim ension

crossover in spin physics. These features are shown in Fig.3b and discussed below, where Q_0 denotes the value of Q for t = 1; i.e. at T = 0:

We rst consider right at the decoupling point $J_0 = K$ = 2 (point C in Fig. 3b), so that $Q_0 = 0$ at T = 0: As T increases, t decreases and Q becom es increasingly positive, the planes become increasingly coupled, in plying a crossover from 2D to 3D. However, this crossover is exponentially slow at low T; and since Heisenberg spins cannot order at any T > 0 in 2D, the spin LRO is im m ediately destroyed at in nitesim al T. As tem perature increases, Q becom es large enough that T_c (Q) exceeds T, and there is a reentrant transition into an anisotropic GS phase. The restoration of spin LRO due to tem perature induced dimension crossover can be viewed as a novel kind of order by disorder m echanism. For $Q_0 > 0$ but sm all (reqime V), the physics is basically the same with one di erence. Since now $T_{c}(Q_{0}) > 0$; the GS order is stable at low T but will disorder for T & $T_c(Q_0)$:

The behavior is even richer for $Q_0 < 0$ but small (regimes III and IV). Now as T increases, Q gets rst less negative, becom es 0 at som e tem perature T_2 ; then becom es positive. That is we have dim ension crossovers rst from anisotropic 3D to 2D and then back to anisotropic 3D as T increases. Correspondingly, the spins rst undergoes a transition from CS LRO to CS short ranged order at T $T_{c}(Q_{0})$: The interplane ferrom agnetic correlation continues to decrease as T increases, crossing over into GS short-ranged order for $T > T_2$: In regime IV, there is yet another reentrant transition into an isotropic GS LRO. Throughout regimes $\rm III-V$, the PS phases has short-ranged spin correlations that are spatially anisotropic and so break the lattice rotational symmetry. In e ect, these are orbital driven spin Peiriels phases. Eventually, in all these regimes, the system switches back in a rst order jump back into isotropic GS ordering when the orbital becom es disordered. Point X is where this transition coincides with the dimension reduction tem perature T_2 ; so an azingly there is a jum p directly from isotropic 3D behavior just above the transition to exactly 2D just below .

In sum m ary, we have investigated the problem of the interplay between spins and orbitals in transition m etal oxides concentrating on the competition between spin-spin interactions and spin-orbital coupling. In addition to illum inating the phase transition properties of m agnetic ordering in insulating V_2O_3 ; our m odel shows a m echanism for dynam ically generated dimensional reduction and dimension crossover. A line of the results presented are for S = 2; the same qualitative behavior will hold for other S: A lso, while our calculations are restricted to the H am iltonian (Eq. 1), these e ects will be present in other spin-orbital m odels as long as orbital ordering results in vanishing spin-spin coupling in one or more spatial directions. Since these dimensional reduction and crossover e ects are present only close to the decoupling point, to observe them one would need to nd systems with the appropriate Hund's coupling so as to produce the proper $J_0=K$ range. For S = 2; there is the additional problem that this range is very narrow. Larger range will occur for sm aller S. Therefore it will be interesting to search for e ective S = 1=2 peroskite transition m etal oxides with double orbital degeneracy and weak Jahn-Teller coupling.
