#### Abstract

W e present com puter sim ulations to exam ine probability distributions of gyration radius for the no-thickness closed polym ens of $N$ straight seg$m$ ents of equal length. W e are particularly interested in the conditional distributions when the topology of the loop is quenched to be a certain knot K . The dependence of probability distribution on length, N , as well as topological state K are the prim ary param eters of interest. O ur results con $m$ that the $m$ ean square average gyration radius for trivial knots scales with N in the sam e way as for self-avoiding walks, where the cross-over length to this "under-knotted" regim e is the sam e as the characteristic length of random knotting, $\mathrm{N}_{0}$. P robability distributions of gyration radii are som ew hat $m$ ore narrow for topologically restricted under-knotted loops com pared to phantom loops, m eaning knots are entropically $m$ ore rigid than phantom polym ers. W e also found evidence that probability distributions approach a universalshape at $\mathrm{N}>\mathrm{N}_{0}$ for all sim ple knots.

1. Introduction
1.1. T he goal of this work

C onsider a random closed polygon of som e N segm ents, all of equal length '. $W$ hat is the probability $w_{\text {triv }}(\mathbb{N})$ that this polygon, considered as a closed curve em bedded in 3D, is topologically equivalent to a circle, that is, represents a trivial knot? W hat is the probability $\mathrm{w}_{\mathrm{K}}(\mathbb{N})$ that it represents a knot of any other kind, $K$ ? Such questions arose rst in the context of DNA ${ }^{\text {nin }}$ and other polym ens $s^{2}$, and continue to attract signi cant attention to the present day. A though a large boody of inform ation has accum ulated,
 ing of these questions rem ains elusive, despite their elem entary form ulation.
$M$ eanwhile, a new set of questions cam $e$ to the forefront in the last
severalyears.F or instance, what is the conditional probability density of the loop gyration radius given that its topology is xed to be K? A sa rst step, what is the average gyration radius of the loop w th the given knot state $K$ ? $T$ his latter question $w$ as rst discussed py, des $C$, Iqizeau' ' $^{\prime}$ and then re-visited theoreticaly eld is partially driven by the idea, rst conjectured in the worlf, that topologicalconstraints acte ectively like self-avoidance, leading to the nontrivial scaling $h R_{g}^{2} i \quad N^{2}$, where is the critical exponent know $n$ in the theory of self-avoiding walks, $0: 588 \quad 3=5$.

The distinction betw een the tw o groups of questions can be ilhum inated by the com parison $w$ th the concepts of annealed and quenched disorder, well known in the physics ofdisordered system $s$ (see, for instance, book ${ }^{1{ }^{16}}{ }^{\text {a }}$ ). If the loop is phantom, i.e. if it can freely cross itself, then its topological state is annealed. In this case, we can ask w hat the probability is to observe a certain topologicalstate $K$. For the loop which is not phantom and cannot cross itself, the knot state is frozen, or quenched, and w e can discuss physical properties of the loop, such as its size or entropy for every given knot state K .

The m ain goal of this paper is to look m ore closely at the probability distributions of the gyration radius of the loops w hich are topologically constrained but not constrained otherw ise. In section ", w, we provide an overview of the previous results about the $m$ ean square averaged gyration radius as wellas som e related questions ofm ethod and sim ulation technique. W e shall concentrate on the relatively sim ple knots, such as $0_{1}, 3_{1}$, and $4_{1}$, form ed by rather long polym ers, w ith N up to 3000 . U sing the term inology introduced in the recent w ork ${ }^{n / 1}$, w e can say we shall.be interested $m$ ostly in the underknotted regim e. T his term inology $m$ akes sim ultaneous use ofboth annealed and quenched view s of polym er topology. The idea is as follow s. C onsider realpolym er loop w ith som e quenched knot $K$. It is considered over-knotted if upon topological annealing, allow ing loop states to be sam pled w ithout topological constraints, the loop is likely to becom e topologically sim pler than K. O therw ise, the loop is considered under-knotted. R oughly, loop is under-knotted if it "w ants" to have m ore knots, and it is over-knotted if it "wants" to have fewer knots. $W$ hether a quenched loop is over- or underknotted depends on the num ber of segm ents, $N$, and, in general, on som e other conditions, such as solvent quality and the like. It is because the loop is under-knotted that it may swell, even if there is no exchuded volum e or self-avoidance. H ere, how ever, term inology clari cation is in order.
1.2. Som e term inology: non-phantom polym ers and self-avoiding polym ers are two di erent things

W e should rst em phasize the di erence betw een concepts of self-avoiding polym ers and non-phantom polym ers. These two concepts are quite frequently confused. The idea of self-avoidance alw ays involves certain nite non-zero length scale, let say $d$, such that tw o pieces of a polym er cannot approach each other closer than d.For instance, if one thinks of a polym er as a little garden hose, then $d$ is its diam eter. R eal polym ers, of course, alw ays have som e exchuded volum e, or som e thickness d. O n the other hand, polym ers which we callphantom are im agined to be able to sw itch from an under-pass to over-pass con form ations, but, im portantly, nether form er nor later state violate the self-avoidance, or exchuded volum e, condition. Speaking about phantom polym ers, we should intentionally close our eyes on the process-how the polym erpasses from under-to over-state. T hisquestion is irrelevant w hen we address probabilities or equilibrium statisticalm echanics. In som e sense, the idea of a phantom polym er can be illustrated by the properties of DNA double helix in the presence of topo-II enzym ei ${ }_{2}^{17 .}$. Of course, this question of crossing $m$ echan ism becom es decisive if one $w$ ants to look at polym er dynam ics w thout enzym es; for the studies of dynam ics, the phantom m odel is m eaningless, one should think in term s of reptation instead ${ }^{12} 8^{18}$.

On a m ore quantitative level, it is know $n$ for the polym er with $N$ seg$m$ ents of the length ' and diam eter d that the excluded volum ee ect does not lead to appreciable swelling as long as N $\quad(=d){ }^{2}$ (see, e.g., book ${ }^{1911}$, page 91). For dsD NA at a reasonable ionic strength, this implies chain length up to about 2500 segm ents, or 75000 base pairs. In this sense, our testing of loops up to $\mathrm{N}=3000$, although dictated by our com putational possibilities, is also $m$ eaningful for the im portant particular case of DNA. On this length scale, it is quite reasonable to neglect the self-avoidance condition, and at the same time to work w th the polym er which is not phantom, because its topological state is quenched (unless enzym es are present).
2. B rief overview of our recent work ${ }^{11}-1$

O ur m ost recent work has investigated the average size of knotted loops. T he in itial focus w as on those loops w ith trivial knot topology, denoted $0_{1}$, as their size has been addressed theoretically ${ }^{\text {chana }}$. In collecting data through sim ulation we were able to gather statistically signi cant inform ation about
severalother knots of low prim e crossing num ber, speci cally, 3, $4_{1}, 5$ and $5_{2}$ knots.

### 2.1. S im ulation m ethods

Like othersi com pute the gyration radius for each of them

$$
\begin{equation*}
R_{g}^{2}={\frac{1}{2 N^{2}}}_{i=1 j=1}^{X^{N}} X_{i j}^{N} ; r_{i j}=\mathfrak{r}_{i} \quad \text { rg } j ; \tag{1}
\end{equation*}
$$

$\mathscr{x}_{i}$ being the position vector of the joint num ber $i$, and then analyze the generated conform ations $w$ th several topological invariants.

O ur loop generation routine is discussed in the Appendix A. Im portantly, the loops are generated w ithout any relation tow ards their topology. W hen a loop is generated, its knot type is assigned. Therefore, we can use the ensem ble of all generated loops to address questions regarding the annealed topology, such as the population fractions of various knots. At the sam e tim e, we are able to determ ine average size, and m ore generally, the probability distribution ofsize for loops assigned any given knot type, which $m$ eans, we can address the quenched topology questions.

To determ ine loop topology we com pute severaltopologicalinvariantsíal. For the loops w ith N 300, we used A lexander invariant ( 1 ) and Vassiliev invariants of degree 2 and $3, v_{2}$ and $v_{3}$. The loop was identi ed as a trivial knot when it yielded $j(1) j=1, v_{2}=0$, and $v_{3}=0$. For longer loops of N > 300, we were able to use only (1) and $v_{2}$ invariants, assigning trivial knot status to the loops with $j(1) j=1$, and $V_{2}=0$. $T$ he details of our com putational im plem entation of these invariants are described elsew here ${ }^{211}$. O fcourse, because of the incom plete nature of topologicalinvariants, our knot assignm ent is only an approxim ation, and surely was som etim es in error.

### 2.2. K not population fractions

W e begin by addressing the annealed topology questions.
Theoretically, it is believed that the probability of a trivial knot is exponential in N :

$$
\begin{equation*}
\mathrm{w}_{\text {triv }}(\mathbb{N})=\mathrm{w}_{0} \exp \left(\mathrm{~N}=\mathrm{N}_{0}\right) ; \tag{2}
\end{equation*}
$$

at least, asym ptotically when $\mathrm{N} \quad$ 1. Such exponential behayior was ob-

is already considered "obvious" by physicists in the, , eld. It is indeed fairly
 recent work ${ }^{251}$ and references therein) of exactly solvable $m$ odel of $w$ inding around a point or a disc in 2 D . This model show sthat typical B row nian trajectory (that is, polym er w th ' ! 0 and $N$ ! 1 ) tends to produce a diverging winding angle, that is, an in nite num ber of tums around the point-like obstacle. It does not seem to require a particularly great leap of im agination to conclude that at very large N som e nite scale knots should be form ed w th a non-zero frequency everyw here along the polym er - and this exactly leads to P oisson-like exponential form ula $\underline{(2)}^{(1)}$ ).

W ith regard to the probabilities of other non-trivial knots, it $m$ ay be argued that they should also be asym ptotically exponential

$$
\begin{equation*}
\mathrm{w}_{\mathrm{K}}(\mathbb{N})=\mathrm{w}_{0}^{(\mathrm{K})} \exp \left(\mathrm{N}=\mathrm{N}_{\mathrm{K}}\right) ; \tag{3}
\end{equation*}
$$

and, m oreover, that characteristic length should be the sam e as that for trivial knots: $\mathrm{N}_{\mathrm{K}}=\mathrm{N}_{0}$. This latter idea can be understood by saying that for every knot, the loop m ust eventually becom e strongly under-knotted if N increases w ithout bound while knot is quenched, Form ula ( $\overline{3}^{-1}$ ) was also tested, albeit by a sm aller num ber of sim ulations ${ }^{514} 3$

In the workl ${ }^{15}$, we $t$ form ula ! (2) to our trivial knot data and found critical length, $N_{0}=241 \quad 0: 6$ and $w_{0}=1: 07, \ldots: 01$. This value of $N_{0}$ is
 volum e radius sent to zero. In other works $N_{0}$ were reported, closer to 300 or 330 . W e interpret this discrepancy as being due to the fact that we exam ined the m odel w ith all segm ents of the
 W e consider it an exciting challenge to understand why these two models exhibit di ering values of characteristic knotting length.

F igure $\overline{1}_{1}^{1}$, show s our sim ulation data for trivial knots fraction, along w ith the data ilhustrating the relative frequency of other knot types. To the accuracy of our sim ulations, we do not see all non-trivial knot probabilities decaying with the sam e characteristic length $\mathrm{N}_{0} . \mathrm{H}_{\mathrm{o}}$ ow ever, we tried to determ ine $\mathrm{N}_{\mathrm{K}}$ (see equation $(\underline{\overline{3}})$ ) by tting the data over sliding window. For instance, Table ${ }_{-1}^{-1}$ shows the $t$ param eters obtained on the interval $500<\mathrm{N}<1150$, or on the interval on $1150<\mathrm{N}<3000$. It is clearly seen that "apparent" characteristic length decreases. A though far from proof, this result is consistent w th the theoretical argum ent behind formula (3) and allow s one to hypothesize that the asym ptotics is just very slow ly achieved.

Table 1. C haracteristic Lengths, $\mathrm{N}_{\mathrm{K}}$

| knot type | $\mathrm{N}_{\mathrm{K}}$ on <br> $(500<\mathrm{N}<1150)$ | $\mathrm{N}_{\mathrm{K}}$ on <br> $(1150<\mathrm{N}<3000)$ |
| :---: | :---: | :---: |
| $0_{1}$ | 241 | 250 |
| $3_{1}$ | 373 | 305 |
| $4_{1}$ | 374 | 307 |
| $5_{1}$ | 375 | 307 |
| $5_{2}$ | 378 | 302 |

Fig.1. The fraction of loops generated w ith trivially knotted topology follow ed the w ell
 the $t$ line at large $N$ is due to the incom pleteness of topological invariants em ployed and re ects contam ination of the supposedly trivial poolw ith som e non-trivial knots. The fractionalpopulation curves for severaldi erent sim ple knot types are show $n$ and labeled. A lthough their overalldecay can be reasonably tby exponents, the characteristic lengths $\mathrm{N}_{\mathrm{K}}$ appear larger than $\mathrm{N}_{0}$, which probably $m$ eans that true asym ptotics are very slow ly ach ieved.

### 2.3. A verage size of di erent knots

### 2.3.1. Scaling of the trivial knot size

W hen averaged over all loops, the $m$ ean square gyration radius, $h R_{g}^{2} i$, is equal to $N^{2}=12$, which is two tim es sm aller than the sim ilar quantity for linear chains (see, for instance, booki'; see also 'Appendix B. A s regards $h{ }_{g}^{2}$ i averaged over only trivially knotted loops, the theoristsid, ${ }^{2}$ that trivial knots develop sw elling behavior for $\mathrm{N} \quad \mathrm{N}_{0}$, in a w ay sim ilar to ob jects which experience excluded volum e forces:

$$
\mathrm{hR}_{\mathrm{g}^{2} i_{\text {triv }}=}^{\mathrm{A}^{2}=12 \mathrm{~N}} \begin{align*}
& \mathrm{A}  \tag{4}\\
& \mathrm{r}^{2}=12 \mathrm{~N}^{2}
\end{aligned} \begin{aligned}
& \text { if } \mathrm{N} \\
& \text { if } \mathrm{N}
\end{align*} \mathrm{~N}_{0} \mathrm{~N}_{0} \text {; }
$$

where scaling power is $0: 589$, and where $N_{0}$ is the sam e param eter introduced in form ula ( $\bar{L}_{1}^{\prime}$ ).

W ewant to em phasize here that the rst line of the prediction, form ula (4, $\overline{4}^{-1}$ ), is not connected to any delicate and thus possibly unreliable theoretical argum ents, but rather com es out of alm ost pure com $m$ on sense. Indeed, when $N \quad N_{0}$, according to form ula $(\overline{\operatorname{Z}})$, there is only m arginalprobability for a phantom loop to have any knot other than trivial. This m eans, the ensemble of trivially knotted loops at these N very nearly coincides w ith the ensem ble of all loops, for which $\mathrm{hR}_{\mathrm{g}}^{2} \mathrm{i}$ is certainly equal to $\mathrm{N}{ }^{2}=12$.

Figure (2) dem onstrates how our sim ulation results are consistent w ith form ula (4) $\left.\mathbf{4}_{1}\right)$. First of all, we see that indeed the $G$ aussian scaling $h R_{g}^{2} i=$ $N^{{ }^{2}}=12$ is recovered at $N$ below $N_{0}$. F itting the data over the interval500< $\mathrm{N}<2500$, we found the param eters, $\quad 0: 58 \quad 0: 02$ and A $0: 44 \quad 0: 03$. It is not only im portant that is consistent with expectations, it is also im portant that the value of pre-factor A provides for sm ooth cross-over betw een regim es at N very close to $\mathrm{N}_{0}$, as expected (because A is very close to $\left.\mathrm{N}_{0}^{1}{ }^{2} \quad 0: 42\right)$.

### 2.32. C orrections to scaling

C an one pull the analogy betw een trivial further? The tem ptation in the eldr data $w$ th a m ore com plex perturbation form ula, $m$ otivated by the analogy w ith the excluded volum e problem ' $\mathbf{I}^{1}$,

$$
\begin{equation*}
h R_{g}^{2} i=A \frac{2}{12} \mathrm{~N}^{2} \quad 1+B \frac{\mathrm{~N}_{0}}{\mathrm{~N}}+\mathrm{C} \frac{\mathrm{~N}_{0}}{\mathrm{~N}}{ }^{2}+::: \tag{5}
\end{equation*}
$$

To understand this form ula, it is useful to recall its appearance in the better know $n$ context of the excluded volum e problem (here, we re-phrase presentation in the book ${ }^{19}$ ). For the excluded volum e (or self-avoiding) polym er, one rst show s that gyration radius can be written in the form $h R_{g}^{2} i=N{ }^{\imath} f(x)$, where $f(x)$ is a universal function of the argum ent $x=$ $\left(d={ }^{\prime}\right)^{\rho} \bar{N}$ (where $d$ and ' are segm ent thickness and length, respectively). For our purposes here, we denote $N_{0}^{?}=(\because=d)^{2}>1$ and then $w$ rite $\mathrm{x}=$ $\left(\mathbb{N}=\mathrm{N}_{0}^{?}\right)^{1=2}$. W hen x is small, $\mathrm{x} \quad 1$, then $\mathrm{f}(\mathrm{x})$ can be presented as an (asym ptotic) perturbation series in integer pow ers of $x . W$ hen $x$ is large, $x \quad 1$, the leading term in $f(x)$ contains the non-trivial scaling power: $f(x) \quad x^{2} \quad 1$, and then the correction term $s$ in this large $x$ asym ptotics involve negative pow ers of $x$, in $m$ ost cases believed ${ }^{14}$, to be integer negative
powers: $f(x) \quad x^{2} \quad 1+B=x+C=x^{2}+:::$. U sing this form ula to w rite $\mathrm{hR}_{\mathrm{g}}^{2} \mathrm{i}$ in term s of $\mathrm{N}_{\mathrm{o}}$ ? , we obtain exactly the equation (둔) ( w ith $=1=2$ ).
$T$ his consideration show $s$ that for the excluded volum e problem form ula $(\underline{1})$ is only valid at $\mathrm{x} \quad 1$, or $\mathrm{N} \quad \mathrm{N}{ }_{0}^{?}$. It is not an interpolation form ula valid across the cross-over region $x \quad 1$; it does not connect tw o asym ptotics sm oothly. For the latter reason, it cannot be considered an interpolation for trivial knots. T hat is why we think it is not correct to $t$ the sim ulation data to this formula in the range of N other than $\mathrm{N} \quad \mathrm{N}_{0}$ (or at least $\left.\mathrm{N}>\mathrm{N}_{0}\right)$.

U nfortunately, our data do not allow for reasonable $t$ to this form ula even in the range $\mathrm{N}>\mathrm{N}_{0}$. The reason is seen in the fact that our data represent a curve which seem $s$ to keep bending upwards as N increases, while form ula ( $\bar{r}_{1}^{\prime}$ ) im plies saturation of the log-log slope to that dictated by the power 2 . A mechanical attem pt to $t$ the formula to the data yields physically $m$ eaningless values for which are greater than unity.

C urrently we do not know why data do not t form ula ${ }^{(1)}(\mathbf{5})$. O ne reason $m$ ay be sim ply poor statistics and noisy character of data at large $N$. It $m$ ight also be an indication of the knot pool contam ination at large N because of the incom pleteness of topological invariants. This is possible, but, in our opinion, not very likely given that trivial knot fraction does not deviate $m$ uch from the exponential $t$ (see Figurelit). In the wonk ${ }^{9}$, we attem pted to address this question deeper, introducing the correction for the errors in knot assignm ent. It did not yield much change in term s of $h R_{g}^{2} i, m$ aking us a bit $m$ ore con dent that the problem $m$ ight be som ew here else. For instance, it is possible that the form ula ( ${ }^{(51)}$ ') does not apply to trivial knots, indicating som e restricted applicability of the very analogy betw een trivial knots and excluded volum e polym ers. M uch work w ill be necessary to clarify this issue.

### 2.3.3. A veraged sizes of non-trivial knots

O urm easurem ent of the swelling of non-trivialknots_is_shown in gure ${ }_{1}^{\prime}(\$)$. It is overall consistent w ith ndings by earlier works sim ple knots cross over from an over-knotted state, in which they are m uch sm aller than the average sized loop to an under-knotted state in which they seem to approach the scaling of trivial knots in an asym ptotic fashion. The inset in this in age show $s$ this asym ptotic approach in the form of a sm all param eter, $=1 \quad h R_{g}^{2} i_{k}=h R_{g}^{2} i_{0}$ decaying $w$ ith increasing $N$.

Fig. 2. Gyration radius averages over trivially knotted loops. The trivial knot average exhibits power law behavior at large $N$ sim ilar to that experienced by polym ers which have excluded volum e. The trivial knot data is system atically larger than the average over all loops, show $n$ as the solid line in the gure. This topology driven sw elling is reeen to develop beyond the critical length about $N_{0}=241$. Independently collected datal ${ }^{2 / 11}$ is show $n$ by stars (?) and agrees w ith our results.

Fig. 3. Log-log plot of the $m$ ean square gyration radius, $h R_{g}^{2} i_{K}$, of knot type $K$, norm alized by the topology blind average over all loops for several particular knot types. $T$ he inset, which show s the ratio of a particular knot gyration radius to the trivial knot gyration radius, $1 \quad \mathrm{hR}{ }_{\mathrm{g}}^{2} \dot{i}_{\mathrm{K}}=\mathrm{hR}{ }_{\mathrm{g}}^{2} \mathrm{i}_{0}$, dem onstrates that all knots rem ain sm aller than, but approach the size of, trivial knots.
3. P robability distributions of the loop sizes

O ur data allow us to $m$ ake one $m$ ore step and to look not only at the averaged value ofR ${ }_{g}^{2}$ for trivialand som e non-trivialknots, but also at the entire
probability distributions. W e were able to generate and analyze histogram s of quality (i.e. looking $s m$ ooth when plotted, a $m$ inim um of $10^{5}$ loops for each curve) for loops of size $N$ 1200. P redictably, the probability distributions are di erent for di erent topological classes, such as all loops versus loops of a certain knot type K. A lso predictably, the probability distributions of $\mathrm{g}_{\mathrm{g}}^{2}$ spread out as N increases. The latter observation suggests the idea of looking at the probability distributions of the re-scaled variable
$=R_{g}^{2}=h R_{g}^{2} i$, where the norm alization factor $h R_{g}^{2} i$ is taken separately for each $N$ and for each topologicalentity.

O urmain ndings are sum $m$ arized in gures (4), present probability distributions $P$ ( ) for the trivialknots $0_{1}$ ( ), trefoils 3 ( ), and $4_{1}$ knots (2). In the same gures we plot also for com parison the analytically com puted probability distributions for linear chains and for all loops. For linear chains, the necessary distribution $P$ chain ( ) w as found by Fixm an a long tim e aga ${ }_{-1}^{28}$; as described in ${ }^{\text {Appendix }}{ }^{-1}$, we were able to derive a sim ilar expression for the probability distribution over all loops, irrespective of topology. To avoid overloading the gures, we do not show the corresponding data points obtained for linear chains and for all loops, but they all sit essentially on top of the theoreticalcurves (con m ing once again the ergodicity of our loop generation routine).

C om paring the shapes of probability distributions for allloops and those w ith identi ed quenched topology, w e notice that the latter distributions are som ew hat m ore narrow. W e em phasize, that although the ect looks sm all for the eye, it is wellabove the error bars of ourm easurem ents. This m eans sim ple knots are less likely to swell much above their average size than other knots, and they are also less likely to shrink far below their average, again com pared to other knots. F igures, $\overline{4}$ and ${ }^{-1} 1$ large and sm all lim its of. In the region $<1.25$ the general notion that entropic sti ness goes w ith topological com plexity seem $s$ to hold true, ie. $m$ ore com plex knots arem ore di cult to stretch or com press than anbitrary loops of the sam e num ber of segm ents. T hat the opposite ofthis seem s to be true in the large region is a subtlety not yet fully understood. In any case, topology blind loops are by de nition always m ore exible than topology speci c loops.

The sm all lim it is of particular interest given its relation to all problem s involving collapsed polym ers, such as proteins. A closer view of the $s m$ all $\mathrm{R}_{\mathrm{g}}$ region of the probability distribution is presented in the F igure '전. $T$ here, the probability distributions are plotted in the sem i-log scale against and, in the inset, against $1=. T$ his can be also understood as the plot
of "con nem ent" entropy, which corresponds to the squeezing the polym er to $w$ th in certain (small) radius. T he reason why we plot the data against $1=$ is because both $P_{\text {chain }}()$ and $P_{\text {loops }}()$ at $s m$ all have asym ptotics
 con nem ent entropy $1=$, and which can due established by a sim ple scaling argum ent, as described, e.g., in the book ${ }^{\prime \prime \prime}$ (page 42). This $1=$ behavior is seen clearly in Figure ( $\overline{1}_{1}^{\prime}$ ). Furtherm ore, we see indeed that com pressing any speci cknot, trivial or otherw ise, is signi cantly more di cult than com pressing a phantom loop. A nalytical expression of entropy for knots is not known, thus far only the $\mathrm{R}_{\mathrm{g}}{ }^{3} \quad{ }^{3=2}$ scaling at sm all has been con jectured ${ }^{29 \prime}$. A though our data is qualitatively consistent w ith this prediction in term $s$ of the direction of the trend, $m$ ore data is needed for quantitative conclusion.

Fig. 4. T he probability density plot for chains ${ }_{2}^{281}$ (line), all loops (another line), and loops w ith certain knots $\left(0_{1}-, 3-, 4_{1}-2\right)$ in the range of large $>1 . D$ istributions are_presented in term $s$ of the scaling variable $=R_{g}^{2}=h R_{g}^{2} i$. $T$ he asym ptotics calculated in Appendix $B$, equations $(B .12)$ and ( $\left.B .13_{1}^{\prime}\right)$, are shown in the gure as dashed lines.

M ore detailed com parison of probability distributions for di erent knots and di erent $N$ are presented in the $F$ igure 5 . This gure show s a num ber of di erent probability curves under di erent conditions. T he left colum $n$ of this gure com pares the topology of di erent ob jects while holding the length of the ob jects constant. The right colum n of the same gure show s com parisons of di erent lengths of the sam e topology. Signi cant in Figure ( ${ }^{( } \bar{\sigma}_{1}$ ) is the suggestion that probability distributions for di erent knots becom every sim ilar ifnot identicalw ith increasing $N$. Indeed in the left col-

Fig. 5. The probability density plot for chains $\operatorname{Li}_{1}^{1 /}$ (line), all loops (another line), and loops w ith certain knots $\left(0_{1}-, 3-, 4_{1}-2\right)$ in the range of sm all < 1.D istributions are presented in term s of the scaling variable $=R_{\mathrm{g}}^{2}=\mathrm{hR}{ }_{\mathrm{g}}^{2} \mathrm{i}$. T he asym ptotics calculated in ${ }^{\prime} A p p e n d i x ~ B_{v}^{\prime}$, equations $\left(B \cdot 12^{\prime}\right)$ and $\left(B .13_{1}^{\prime}\right)$, are shown in the gure as dashed lines. In set: Sem i-log probability density plot (or linear entropy plot) at sm all against $1=$.
um $n$ in $F$ igure $\bar{\sigma}_{1} \overline{6}$, it is di cult to see the di erence betw een the distributions for the three distinct topologies for $\mathrm{N}=1200$ or even for $\mathrm{N}=660$.Oneway to understand thise ect is to consider the notion ofknot localizationn in in $T$ he idea is that every strongly under-knotted loop at large $N$ places its knot in som e sm all fraction of its length, thus looking like a trivialknot, w ith a sm all bum $p$ where the appropriate crossings reside. The collapse of $P_{K}()$ fordi erent, sim ple knot types, $K$, to one curve at large $N$ is consistent $w$ ith this concept of localization. At the sam e tim e, Figure ${ }_{6}{ }_{6}$ suggests that probability distribution $P_{K}()$ for each knot keeps evolving with $N$ changing over the cross-over region at $\mathrm{N} \quad \mathrm{N}_{0}$.

## 4. C oncluding rem arks

To sum $m$ arize, in this paper we presented com putational results on knots in zero thickness loops ofN rigid segm ents ofequallength '. To the accuracy of our $m$ easurem ents, our data are consistent $w$ ith the idea that $m$ ean square gyration radius averaged over the loops w hich are topologically equivalent to trivial knots is larger than the sim ilar quantity averaged over all loops irrespective oftopology. T he extent of this additionalsw elling appears sim ilar to the swelling of self-avoiding walks com pared to $G$ aussian random walks. Sw elling is characteristic not only of trivial knots, but in general for under-knotted loops, in the sense that a topologically quenched loop sw ells

Fig. 6. The probability distributions, P ( ) for several di erent lengths, N. Left C olum $\mathrm{n}: \mathrm{C}$ ollapse of severaldi erent topologies to one curve at large N , (com pare $\mathrm{N}=660$ or 1200 to $\mathrm{N}=90$ ), im plies that one $m$ aster curve for under-knotted loops exists, and that it is visible for $0_{1}, 3_{1}$, and $4_{1}$ knots at $N \quad 660$. R ight C olum n : C urves for these sim ple topologies, as they di er in length, are certainly $m$ ore sim ilar to each other than they are to the average of all loops. M ovem ent of the curves as N changes is not yet understood.
if its knot state would have simpli ed upon annealing of its topology. We have exam ined not only averaged gyration radius, but also its probability distribution.W e found that topologically under-knotted loops are relatively unlikely to deviate far from their average sizes, either to sm aller or to larger sizes.W e have also found indication that the probability distribution of the gyration radius of sim ple knots becom es universal for all under-knotted loops when their length exceeds certain threshold. Im portantly, our data
con $m$ the existence of a cross-over at $N$ of the order of $N_{0}$, the characteristic length of random knotting: it is only at $N>N N_{0}$ that there is analogy betw een under-knotted loops and self-avoiding walks, at $\mathrm{N}<\mathrm{N}_{0}$ topological constraints have only a marginale ect on the trivial knots.

H ow far does the analogy go betw een self-avoiding polym ers and topologically constrained ones? W e were unable to con $m$ this analogy beyond sim ple scaling; it is unclear whether the $h{ }_{g}^{2} i$ dependence on $N$ approaches its scaling form $\mathrm{N}^{2}$ in the sam $e m$ anner as it happens for self-avoiding walks. It is worth em phasizing that there is a eld theoretic form ulation for the self-avoiding walk s $^{35}$, but there is nothing of th is sort for knots. In our opinion, it rem ains an exciting challenge to nd a solid understanding of the connection betw een uctuation properties of the loop and its topology.

## A cknow ledgm ents

W e thank A.Vologodskii for sharing with us his unpublished data ${ }^{27 \prime}$, and T D eguchi for useful discussions. This work was supported in part by the M R SEC P rogram of the N ationalScience Foundation underA ward N um ber D M R - 0212302 .

A ppendix A. Loop generation
W e generated loops of the length N divisible by 3 using the follow ing $m$ ethod. To produce one loop, we generated $\mathrm{N}=3$ random ly oriented equilateral triangles of perim eter $3^{\prime}$. .W e consider each triangle a triplet of head-to-tail connected vectors. Collecting all $N$ vectors from $N=3$ triangles, we re-shu ed them, and connected them alltogether, again in the head-to-tail $m$ anner, thus obtaining the desired closed loop.

A sim ilar sim pler m ethod applicable for even $N$ and re-shu ing vectors obtained from zero sum pairs often yields the loops w th overlapping nodes. $T$ his happens when the re-shu ing results in the succession of som e $2 \mathrm{~m}<$ N vectors belonging to exactly $m$ pairs and thus form ing the zero sum (i.e., closed) sub-loop. T he probability of such an event is oforder unity, because the probability for the two vectors from the sam e pair to be next to each other after the re-shu ing, scales as $1=\mathrm{N}$, and there are N such pairs; m ore accurate calculation ${ }^{26}$ - show s that th is probability approaches $1 \quad 1=e$ as N ! 1 .

For the triangles, the problem is not in any way as severe, because the probability for the three vectors of the triplet to be next to each other scales as $1=\mathrm{N}^{2}$, while the num ber of triangles is still N , so the overlapping loops

Fig. 7. The fraction of generated loops which overlapped with in the resolution of com putational accuracy. If a set of $N=s$ polygons, where polygons have s sides, is used to generate a walk of length $N$, the fraction of generated loops, $N^{2} \mathrm{~s}$ willoverlap exactly. $T$ his behavior is seen in the im age.
are rare as $1=\mathrm{N}$ (and the probability to have two, or, in general, $m$ triplets to occupy com pletely the 3 m stretch of the re-shu ed sequence does not change the $1=\mathrm{N}$ estim ate).

O ur test $m$ easurem ents of the fraction of loops overlapping generated w ith pairs, triplets, and pentagons of vectors (squares are 2 pairs), show $n$ in gure $\overline{(1-\gamma)}$, agree with this understanding. $W$ e see in this gure that the fraction overlapping at a certain $N$, when generated in polygons of $s$ edges scales like $N^{2}$ s. W e chose to generate w ith triplets to avoid the constant overlap im plied by pairs, as well as avoiding the correlation im plicit $w$ th larger sets of objects. A though generated with our $m$ ethod, these loops are not $m$ em bers of the set analyzed as they are not single stranded loops devoid of self-intersections, but rather a di erent physical class of ob jects w ith "petals." The simple exam ple of $N=9$, see gure ${ }_{1}^{\prime}(\beta)$, ilhustrates this. Suppose that the three triangles generated have segm ent vectors, $\left(a_{1} ; a_{2} ; a_{3}\right)$; $\left(\tilde{b}_{1} ; \tilde{b}_{2} ; \tilde{o}_{3}\right)$ and $\left(a_{1} ; a_{2} ; a_{3}\right)$. By de nition, each set ofvectors w th in a triangle sum s to zero, for exam ple, $c_{1}+c_{2}+c_{3}=0$. A walk is then created by a random perm utation of all of the segm ent vectors, for exam ple, $\left(a_{3} ; a_{2} ; a_{1} ; \tilde{b}_{1} ; a_{2} ; \tilde{x}_{3} ; \mathfrak{c}_{1} ; \tilde{b}_{2} ; \mathfrak{c}_{3}\right)$. The problem of overlapping, described above, occurs whenever the elem ents of one orm ore com plete triangles occurw ithin a continuous section of the perm utation vector. This subsection form s a com plete loop, as does the rest of the chain and instead of a single loop, one has a diagram which looks som ething like a owerwith multiple
petals com ing o of a center axis or set of axes.

Fig. 8. O ur generation routine can produce errant ob jects which are not loops.

In practioe, there was also a totally di erent problem. At large $N$, our knot identi cation routine was som etim es failing because of the perceived triple crossing on the projection. A sim ple rotation by random Euler angles resolved this projection problem in all cases.

A ppendix B . P robability distribution of all loops
In this A ppendix we address the problem which, of its ow $n$, does not belong to the sub ject of knots. N am ely, we consider a phantom loop, which can freely pass through itself, and determ ine the probability distribution of its gyration radius. In other, equivalent, words we consider the distribution of sizes over the ensem ble ofallpossible loops of the given num ber of segm ents, $N$, irrespective of their topology. O ur approach here closely follow s that of the work ${ }^{284}$ by $F$ ixm an, where he detem ined probability distribution for the gyration radius of the linear chains. To m ake our work self-contained, we reproduce below the $m$ ain steps of $F$ ixm an derivation along with our results for phantom loops.

To begin with, we sim plify the problem by transform ing it from the gyration radius of a chain or a loop with N rigid segm ents of xed length
' to the sim ilar problem with a sm aller num ber of G aussian distributed segm ents. To achieve this, we group $N$ segm ents in $n$ blobs of $N=n$ segm ents each. W e denote $a s b_{k}$ the end-to-end vector of each blob labeled $k$, where $\mathrm{b}^{2}=(\mathrm{N}=\mathrm{n})^{12} . \mathrm{N}$ ote that m pan squared gyration radius, which is well know n for both chains and loop ${ }^{19}{ }^{19}$, can be expressed in term $s$ ofeither $N$ and 'or $n$ and $b: h R_{g}^{2} i_{\text {chain }}=N^{2}=6=n b^{2}=6$ for chains and $h R_{g}^{2} i_{10 o p}=N^{2}=12=$ $\mathrm{nb}^{2}=12$ for loops.

If $\mathrm{N}=\mathrm{n} \quad 1$, then probability distribution for the unitless vector $\sim$ is Gaussian, w ith zero $m$ ean and unit variance: $g(\sim)=$ $(3=2)^{3=2} \exp \quad 3^{2}=2$. If, at the sam e tim e, n $\quad 1$, then com puting the gyration radius ( $\overline{1} 1)$ we can replace each blob w th the concentrated $m$ ass $\mathrm{N}=\mathrm{n}$ sitting, say, at the beginning segm ent of this blob. Then, form ula (1, $1_{1}^{\prime}$ ) can be transform ed to have just $n$ (instead of $N$ ) points, where now
 quadratic form of the vectors eta. It is convenient to write it in the form

$$
\begin{equation*}
\frac{R_{g}^{2}}{h R_{g}^{2} i}=A{ }_{k ; m=1}^{X^{n}} G(k ; m) \sim_{k} \quad m^{\sim} ; \tag{B.1}
\end{equation*}
$$

where coe cient A is di erent for chains and loops and can be determ ined at the end to ensure the correct average ( $\mathrm{h} i=1$ ), and where kemelG ( $\mathrm{k} ; \mathrm{m}$ ) is as follow s:

$$
G(k ; m)=\frac{k}{n^{2}} H\left(\begin{array}{ll}
m & k
\end{array}\right)+\frac{m}{n^{2}} H(k \quad m) \quad \frac{k m}{n^{3}} ; H(x)=\begin{aligned}
& 8 \quad \text { for } x>0 \\
& 1=2 \text { for } x=0 \\
& 0
\end{aligned} \text { for } x<0 .
$$

(B 2)
W e now note that the probability of the chain conform ation speci ed by blob end-to-end vectors $\mathrm{b} \sim_{1} ; \mathrm{b} \sim_{2} ;::: ; \mathrm{b} \sim_{\mathrm{n}}$ is given by

$$
Z_{\text {chain }}(£ \sim g)=Y_{k=1}^{Y^{1}} g\left(\sim_{k}\right):
$$

Sim ilar probability for the loop reads

$$
Z_{\text {loop }}(f \sim g)=\sum_{k=1}^{Y^{n}} g\left(\sim_{k}\right) \quad X_{k=1}^{n} \sim_{k}^{n} \quad \frac{2 n^{3}}{3=2}: \quad \text { (B.4) }
$$

C om pared to the distribution for the chains, w e have here onem ore factor $g$, describing the connection betw een chain head and tail, $m$ aking the loop; we have -fiunction ensuring loop closing; and we have also the norm alization factor.

N ow, in order to com pute probability distribution of , we introduce the characteristic function

$$
\begin{equation*}
K(s)=h e^{i s} i=e^{i s} Z(f \sim g) d f \sim g ; \tag{B.5}
\end{equation*}
$$

where $Z$ is either $Z_{\text {chain }}$ or $Z_{\text {loop }}$. Looking at the expressions for $Z$, (B)
 of vectors ~ decouple. Taking advantage of this decoupling, we can write $K(s)=[f(s)]^{3}$, where

$$
\begin{aligned}
& f_{\text {chain }}(s)=\frac{3}{2}^{(n \quad 1)=Z^{Z}} \exp \frac{3}{2}_{3_{k=1}^{1}}^{{ }_{k}^{2}+} \\
& \mathbb{X}^{1} \mathrm{G}(\mathrm{k} ; \mathrm{m})_{\mathrm{k} \mathrm{~m}^{5}} \mathrm{~d}_{1} \mathrm{~d}_{2}::: \mathrm{d}_{\mathrm{n}} 1 \quad \text { (B .6) } \\
& +\left\{S_{k ; m=1} G(k ; m)_{k m^{2}} 5 \mathrm{~d}_{1} \mathrm{~d}_{2}::: \mathrm{d}_{\mathrm{n}} \mathrm{I}^{(\mathrm{B} .6)}\right.
\end{aligned}
$$

for chains, and
for loops. In the later case, we have used the integral representation of the -finction, thus the extra integration over $p$. These $G$ aussian integrals are easy to evaluate, because the $m$ atrix $G(k ; m)$ is diagonalized, (we have om itted detail $\left.{ }^{2}{ }^{28}\right)$, by the unitary $m$ atrix $C(k ; m)=P \overline{2=n} \sin (k m=n)$, revealing the eigenvalues of the $G \mathrm{~m}$ atrix, $1=\mathrm{k}^{2} 2 \mathrm{w}$ th allinteger k from 1 to $n$. U pon som e algebra, we obtain for chains
$w$ here $z^{2}=2\{A s=3$. Sim ilar $m$ anipulations for loops involve an extra inte-
gral over p:
where again $z^{2}=2\{A s=3$. Finally, we choose coe cient A based on the condition $\mathrm{h} i=1$, or $\mathrm{K}^{0}(\mathrm{~s})_{\mathrm{s}=0}=\{$. This yields $\mathrm{A}=6$ for chains and $\mathrm{A}=12$ for loops. $T$ herefore, we nally get

$$
\begin{equation*}
K_{\text {chain }}(s)=(\sin z=z)^{3=2} ; \quad z^{2}=4\{s ; \tag{B.10}
\end{equation*}
$$

(the result due to Fixm an $n^{-2^{-1}}$ ), and

$$
\begin{equation*}
K_{\text {loops }}(s)=(2 \sin (z=2)=z)^{3} ; \quad z^{2}=8\{s: \tag{B.11}
\end{equation*}
$$

K now ing K (s), nding the probability distribution $P()$ is the $m$ atter of inverse Fourier transform . N um erical inversion of Fourier transform s yield

A nalytically, asym ptotic expressions can be found for both sm all and large . For chains, Fixm an ${ }^{281}$ found

$$
P_{\text {chain }}()^{\prime} \quad \begin{align*}
& \frac{{ }^{5=2} e^{3=2}}{9 \underline{6}}  \tag{B.12}\\
& 9{ }^{1=2} e^{2} \\
& { }^{3} e^{9=4}(4)
\end{align*} \text { for for } \quad 1 \quad:
$$

Sim ilar expressions for loops read

$$
\mathrm{P}_{\text {loop }}()^{\prime}{ }^{\frac{6}{2}{ }_{\mathrm{q}} \mathrm{Q}^{2}{ }^{2}{ }^{2}=2} \begin{aligned}
& \text { for } \\
& 324{ }^{9=2} e^{9=(2)} \text { for } \\
& 1
\end{aligned}: \quad \text { (B .13) }
$$

To obtain these results, it is convenient to rew rite the inverse Fourier transform :

$$
\begin{equation*}
P_{\text {loop }}=\frac{1}{2}^{Z} K(s) e^{i s} d s=\frac{1}{2}\left\{_{v^{Z}}^{\frac{\sin }{}_{3}^{4}} e^{2=2} d\right. \text {; } \tag{B.14}
\end{equation*}
$$

where in the latter integral $=\mathrm{z}=2$ and integration contour $V$ in com plex -plane is $V$-shaped, runs from in nity along the line $w$ ith argum ent $3=4$ to in nity along the line with argum ent $=4$. In this form, it is conveniently seen that $P_{\text {loop }}()=0$ at $<0$, as it $m$ ust be, since is a positive quantity. Furtherm ore, deform ing the integration contour, we can establish that at

1 the integral is dom inated by the saddle at $\quad 3\{$, while at 1 it is dom inated by the residue at the third order pole in $=$, yielding the results ( $\overline{\mathrm{B}} \cdot \mathbf{- 1 3 1 3 )}$.

On a m ore physical note, it is im portant to realize that the exponential term $s$ in equations $(\bar{B}-12)$ and $[-13)$ at $s m$ all are identical if $w$ ritten in term s of $\mathrm{R}_{\mathrm{g}}, \mathrm{N}$ and ' instead of. Indeed, the leading term of the corresponding entropy (which is $\ln P$ ) is equal to $9 N^{\mathbb{Z}}=24 R_{g}^{2}$ for both chains and loops. A part from the coe cient of $9=24$, the scaling form of this result can be understood based on a sim ple argum ent considering con nem ent of either-a chain or a loop in a cavily of the size $R \quad{ }^{P} \bar{N}$ (see, for instance, book ${ }^{119}$, form ula (72)).

On the other hand, at large chain entropy is $3\left(\mathrm{R}_{\mathrm{g}}\right)^{2}=2 \mathrm{~N}^{\circ}$, while loop entropy is four tim es larger, it is $6\left(\mathrm{R}_{\mathrm{g}}\right)^{2}=\mathrm{N}{ }^{\text {² }}$. This can be understood as follow s . For the chain, rem em bering that entropy of the state w ith end-to-end distance $L$ is $3 \mathrm{~L}^{2}=2 \mathrm{~N}^{2}, \mathrm{Fixm}$ an noted ${ }^{2 g}$ that large $\mathrm{R}_{\mathrm{g}}$ conform ations are dom inated by the sem i-circular shapes with $L=R_{g} \cdot T$ he loop obviously represents tw o such pieces, so loop entropy is tw ige entropy of the half-chain: $6\left(\mathrm{R}_{\mathrm{g}}\right)^{2}=\mathrm{N}^{2}=2 \quad 3\left(\mathrm{R}_{\mathrm{g}}\right)^{2}=2(\mathrm{~N}=2)^{2}$.
