We have studied magnetotransport in arrays of nibbium led grooves in an InAs/AlG aSb heterostructure. The critical eld of up to 2.6 T permits to enter the quantum Hall regime. In the superconducting state, we observe strong magnetoresistance oscillations, whose am plitude exceeds the Shubnikov-de Haas oscillations by a factor of about two, when normalized to the background. Additionally, we not that above a geometry-dependent magnetic eld value the sam ple in the superconducting state has a higher longitudinal resistance than in the normal state. Both observations can be explained with edge channels populated with electrons and Andreev rejected holes.

The analysis of superconductor-sem iconductor structures has been an active eld of research in recent years (see, e.g., Ref. 1 and references therein). The versatility of sem iconductors and the high mobilities attainable in heterostructures in combination with the retrore ecting and phase coherent process of Andreev re ection [2] have allowed to observe a number of unique phenom ena. By now, experiments in the regime of low magnetic elds, i.e. no larger than a few ux quanta per junction area, are well established. G ateable Josephson currents [3], quasiparticle interference [4], phase coherent oscillations [5] and an induced superconducting gap [6] have been observed, to nam e a few.

In the high-eld regime, experimental evidence is much less abundant. A num ber of theoretical papers have dealt with Andreev re ection at high elds [7, 8, 9, 10]. Notably, R ef. 7 describes how edge channels in the quantum Hall regime are formed of electron and hole states. To enter the regime of a fully developed quantum Halle ect external elds of several Tesla are required. Experim ents have been perform ed with high critical eld superconductors, such as N bN [11, 12] or sintered SnAu [13], each of which su er from technological di culties, making the interpretation of the experiments in the quantum Hall reqime di cult. In this work, however, we report clear evidence of the in uence of Andreev re ection on transport in edge states using the well established Nb-InAs system. The critical eld of up to 2.6 T perm its to enter the quantum Hall regime at high lling factors.

For the sample geometry we have chosen an array of niobium led grooves in an InAs-A IG aSb heterostructure containing a high-m obility two-dimensional electron gas (2D EG). A similar arrangement has been studied previously [14, 15] in low magnetic elds. An important difference to single S-2D EG-S junctions is that the voltage

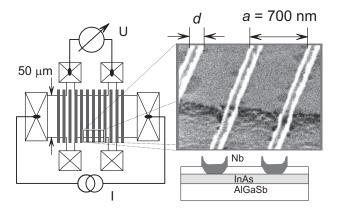

FIG. 1: Left: Geometry for the four-point measurements. Right: A scanning electron micrograph of the sample taken at the mesa edge. A cross section of the sample is also shown.

## probes are located in the 2DEG.

The samples were fabricated from a high-mobility InA s/A IG aSb quantum well, which was grown by molecular beam epitaxy on a GaAs substrate [16]. Mesas of 50 m width and 0 hm ic contacts were prepared using optical lithgraphy. A fter this step an electron density of  $n_s = 1.25 \quad 10^{12} \text{ cm}^2$  and a mobility of = 200000  $cm^2/V$  swere found. The mean free path in this material was therefore 3.8 m, allowing for ballistic transport in nanostructures. The Nb-lled grooves were de ned with electron beam lithography, selective reactive ion etching (RE) of the top A GaSb layer, niobium sputter deposition and lift-o. An in situ argon ion etch prior to the Nb sputtering ensured a high transparency of the Nb-InAs interface (Z = 0.63 in the OTBK -m odel [17]), which allowed to observe several subharm onic gap structures in the di erential resistance at low magnetic elds.

M ore fabrication details can be found in [18]. A scanning electron m icrograph and a schem atic cross section of the sam ple are shown in Fig.1. Lattice periods were ranging from a = 400 nm to a = 3 m with di erent Nb-stripe widths.

The magnetoresistance measurements were done in a four-point conguration, but given the periodic geometry of the sample we electively measured a series connection of many S-2DEG-S junctions. The critical temperature  $T_c$  of the Nb stripes was ranging from 6.9 K to 8.3 K, depending mainly on the stripe width. Figure 2 shows the magnetotransport curves of two samples with lattice periods a = 700 nm and a = 3 m. The Nb stripes were 120 nm wide and 70 nm thick in both cases.

Except for very low elds where the proxim ity e ect dom inates, the curves lie on one of two branches, depending on whether the niobium stripes are in the normalor superconducting state. A transition between both branches is observed in Fig. 2 when the critical eld of the niobium stripes at a given tem perature is surpassed. Both branches cross at a certain magnetic eld (arrows in Fig. 2). At low elds, the resistance on the superconducting branch is lower than on the norm al branch, as expected for high quality contacts. For high elds how ever, the magnetoresistance in the superconducting state is higher than in the norm al state. This behaviour is not due to a low contact transparency, resulting in a reduced Andreev re ection probability. In that case the resistance below  $T_c$  would always be higher than above  $T_c$ . A crossing point would not be observed. In a reference sam ple where the contact transparency was deliberately reduced, the resistance in the superconducting state was indeed higher than in the norm al state throughout the entire eld range.

AtB > 1 Tesla, oscillations appear in the magnetoresistance. In a two-dimensional electron system, magnetotransport oscillations are observed as soon as the m agnetic eld is strong enough such that Landau level quantization is resolved experim entally. Since the critical eld of the niobium lines is much higher than the onset of the oscillations, we observe the impact of Andreev re ection on transport in the quantum Hall regime. On the superconducting branch, the oscillation amplitude is much m ore pronounced than on the norm albranch. This can be seen m ore clearly in Fig. 3, where the data from Fig. 2, right has been replotted versus 1=B, after subtracting the slowly varying part of the magnetoresistance. The increase in amplitude is indeed quite striking. The two main experimental ndings in our samples are therefore the higher resistance at high elds and the strong increase in the amplitude of the 1=B -periodic oscillations.

Let us rst consider the magnetoresistance oscillations in more detail. We evaluated the increase in amplitude for samples with a lattice period a of 1 m, 2 m, and 3 m (data of the latter sample are shown in Fig. 2, right). The oscillation amplitude in the superconducting

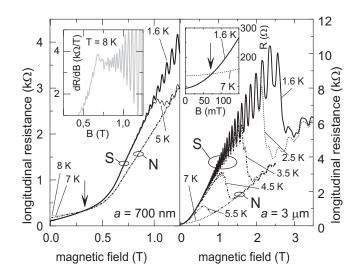

FIG.2: T-dependent m agnetotransport curves for two di erent sam ples. A rrows: crossing points of the graphs above  $T_{\rm c}$  and below  $T_{\rm c}$ . Left inset: The peak in dR =dB corresponds to a change in slope of the resistance trace. R ight inset: Enlarged view of the crossing point for the sample with a = 3 m. The critical tem peratures were 7.4 K (left) and 6.9 K (right). Letters N' and S' denote the norm al and superconducting branch, respectively.

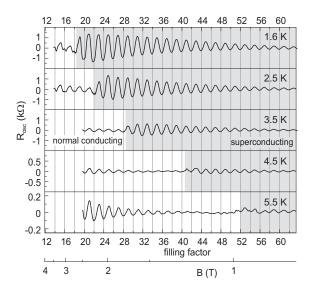

FIG. 3: Same data as in Fig. 2, right, after subtracting the slow ly varying background and plotted against the lling factor. For ease of comparison, the value of B is also given. Shaded regions: Nb stripes are superconducting, as extracted from Fig. 2. N ote the strong increase of the am plitude at the superconducting transition.

case was higher by a factor of 1.45, 4.1, and 6.4, respectively, when the am plitudes slightly above and below  $B_c$ were compared at T = 3 K. Thus, the further the stripes were apart, the more striking the increase in am plitude. The higher oscillation am plitude is not sim ply due to the larger non-oscillatory resistance in the superconducting

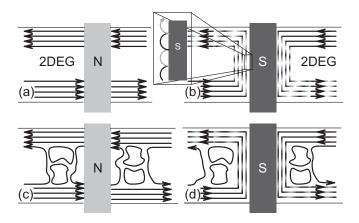

FIG. 4: Edge channels in a 2DEG hosting a norm al (left) or superconducting (right) electrode. (a), (b): Integer lling factor (i.e. resistance m in im um). (c), (d): In between integer lling factors. W ith a norm al electrode, only the innerm ost channel is backscattered due to impurities in the 2DEG. In the superconducting case, edge channels hitting the electrode are Andreev re ected (see inset) and contain electrons and holes (gray). The am ount of current which is backscattered depends on the hole probability, which oscillates in a m agnetic eld.

state, caused e.g. by the higher conductivity of the N b stripes in the superconducting state. Normalized to the increase of the background, the oscillation amplitude still increased by a factor of up to 1.9 in the superconducting case [19] and the dependence on the stripe separation was maintained.

We also tted the temperature dependence of the oscillation amplitude [20]. In the norm al conducting case the amplitude was well described by thermal activation over the Landau gap and gave an e ective mass of  $m_e = 0.04 m_0$ , where  $m_0$  is the free electron m ass. The same e ective mass was found in a sample with the same geometry, but Au stripes instead of niobium. This value is comparable to what is found in InAs-based 2DEGs with a high carrier density [21]. In the superconducting case however, the t was poor and yielded an e ective mass of up to 0:1 m $_0$ , which is far from the real value. Therefore, Landau level splitting alone cannot be the underlying mechanism (and the e ective mass extracted from such a t is meaningless). Instead, edge channels containing electrons and Andreev-re ected holes can lead to the enhanced oscillations, as we discuss now .

Fig. 4 shows a unit cell of the periodic arrangement of metallic stripes in a 2DEG. The edge-channel picture for normal and superconducting stripes is illustrated, both for a full and a half-led Landau level. A norm alconducting metal stripe acts as an ideal contact for electrons propagating in edge channels once the stripe length greatly exceeds the cyclotron radius. This is indeed the case for our experiment. When the stripe is superconducting, the gap for quasiparticle excitations prevents the absorption of a single electron and leads to Andreev re-

ection instead. A sboth electrons and Andreev-re ected holes are forced on cyclotron orbits having the same chirality (see Fig. 4, inset), an edge channel is form ed along a superconducting contact, consisting of a coherent superposition of electron and hole states [7, 8, 9] which is stable along its entire length. The charge current in such an Andreev edge channel is proportional to the di erence between the moduli of electron and hole am plitudes in that superposition [7]. For an ideal 2DEG -S-interface, Andreev re ection is perfect and the Andreev edge channel is com posed of electrons and holes in equal proportions. In that case, no net current is owing along the superconductor edge and the mesa edges rem ain decoupled, i.e. the behaviour of a norm alquantum Hall sample is recovered. However, when an interface barrier and/or a Ferm i-velocity m ism atch leads to a nite amount of normal re ection, interference between normal and Andreev-re ected quasiparticles results in 1=B -periodic oscillations of the electron and hole am plitudes [7, 8]. For nonequal electron and hole am plitudes, a nite current is owing parallel to the superconducting stripe, which is fed into the norm all edge channel at the opposite m esa edge and gives rise to backscattering between the norm alledge channels. Form ally, these am plitudes can be calculated by matching appropriate solutions of the Bogoliubov-de Gennes equations [22] at the interface [7]. A parameter w was de ned in Ref. 7 for characterizing the interface barrier, which corresponds to 2Z in the BTK-model [23]. The hole probability { and therefore the strength of the backscattering { oscillates strongly when w > 0, with the same periodicity as SdH oscillations. This is what we would expect to occur in our sam ples, because even though the interface is highly transparent, there is still a residual barrier.

How can the form ation of Andreev edge channels at an imperfect interface explain the enhanced magnetooscillations observed in our measurements? In a quantum Hall sample with norm al electrodes, the amplitude of the SdH-oscillations is determined by backscattering of the innerm ost edge channel only, i.e. the one which is form ed by the bulk Landau level closest to the Ferm i energy. Therefore the conductivity of the sample can only oscillate by one conductance quantum . If the electrodes are superconducting, alledge channels are subject to Andreev re ection when they hit the electrode. The oscillation amplitude is therefore not limited to one conductance quantum. For example, for w = 1 and = 18(which would correspond to the critical eld of the Nb stripes at 1.6 K), an amplitude of about six conductance quanta was obtained in Ref. 7. The presence of the screening current in the superconductor [24] and disorder [25] does not change this behavior qualitatively for edge channels whose corresponding cyclotron radius is larger than the penetration depth but smaller than the mean free path. These conditions are satis ed for the range of lling factors where the enhanced m agnetooscillations are observed in our sam ple.

In the model treated in Ref. 7, the edge channels moving along them esa edge and hitting the 2D EG-S interface consist of electrons only, since they originate from a norm alconducting electrode. O ur sam ples incorporatem any S-2D EG-S-contacts in series. For short stripe separation, the edge channels im pinging on the 2D EG-S-boundary thus contain both electrons and holes. The situation of Ref. 7 is therefore not realised ideally, backscattering is less e ective and the oscillations are not as pronounced. W ith increasing distance between the Nb stripes, m ore and m ore holes in the edge channel along the m esa edge recom bine with the electrons, resulting in an edge channel containing only electrons as treated in Ref. 7. This explains qualitatively why the oscillation am plitude increases with increasing stripe separation.

Now we turn to the non-oscillatory part of the magneto resistance. The magnetic eld position of the crossover point (arrows in Fig.2) for 16 sam ples was well described by the condition  $R_c = 0.8$  b, where b = a d is the distance between the stripes and  $2R_c$  is the cyclotron diam – eter in the 2DEG.No satisfactory dependence on either the lattice period a or the stripe width d was found. A dditionally, the slope of the magnetoresistance trace (left inset in Fig. 2) changes at  $2R_c = b$  (i.e. one cyclotron orbit ts in between two stripes), which marks the transition to the regime of edge channel transport. The latter is found both above and below T<sub>c</sub>, hence this feature is unrelated to superconductivity. Note that this ballistic picture is justi ed as the mean free path is much larger than the perimeter of a cyclotron orbit at that eld. Since both the crossing point and the change in slope are linked to the distance between the stripes, we conclude that both features are caused by the transition to the edge channel regime.

In the given geom etry, we measure a series connection of m any two-point resistances (m etal-2D EG), shunted to an unknown fraction by the sem iconductor underneath the niobium stripes. Although it is therefore di cult to m ake quantitative statem ents about the resistance we can explain qualitatively why the high- eld resistance in the superconducting case is higher than in the norm al case.

The Hall voltage is shunted by the metallic stripes connecting both sides of the Hall bar. This leads to a quadratic magnetoresistance, which is less pronounced in the normal state when the niobium stripes have a – nite resistance. This description is valid at low elds. At high elds how ever, the magnetoresistance appears to be linear in B, as one would expect for the two-point resistance in the edge channel regime. The two-point resistance is determined by the number of edge channels (which decreases as B increases) and their conductivity, which is constant ( $2e^2=h$ ) in a conventional quantum Hall sam ple. As we have seen above, the edge channels em itted by the superconducting electrodes consist of electrons and holes travelling in the sam e direction. Therefore, the conductivity of an edge channel is reduced compared to the norm al case, which also leads to an increased resistance.

To sum marize, we have exam ined arrays of Nb-lled grooves in an InA s-A IG aSb heterostructure at high m agnetic elds using magnetotransport measurements at various temperatures. We observe strong 1=B-periodic resistance oscillations when the Nb stripes get superconducting. They are due to edge channels containing both electrons and holes. We also nd that above a geometrydependent magnetic eld, the overall sample resistance is higher in the superconducting case than in the norm al case. This nding is consistent with the picture of edge channels containing Andreev re ected holes. Our experiments therefore explore the impact of Andreev re ection on transport in the quantum Hall regime.

The authors wish to thank J.Keller, K.Richter, and C.Strunk for stimulating discussions. Financial support by the D eutsche Forschungsgem einschaft is gratefully acknow ledged.
