Optical properties of GaAsN system with nitrogen concentrations in the range of 0.9-3.7% are studied by full-potential LAPW method in a supercell approach. The E_+ transition is identified by calculating the imaginary part of the dielectric function. The evolution of the energy of this transition with nitrogen concentration is studied and the origin of this transition is identified by analyzing the contributions to the dielectric function from different band combinations. The L_{1c} -derived states are shown to play an important role in the formation of the E_+ transition, which was also suggested by recent experiments. At the same time the nitrogen-induced modification of the first conduction band of the host compound are also found to contribute significantly to the E_+ transition. Further, the study of several model supercells demonstrated the significant influence of the nitrogen potential on the optical properties of the GaAsN system.

PACS numbers: 71.15-m, 71.45.Gm, 71.55.Eq

GaAs_{1-x}N_x alloys have attracted much attention of both experimentalists and theoreticians due to their unusual physical properties. Among those features, observed in the typical nitrogen concentration regime of 0.5%-3.0%, one should mention the anomalous band gap reduction, which makes this system technologically important for such electronic devices as infrared diode lasers [1] and multijunction solar cells [2]. Another striking feature of this system is the appearance of a new composition-dependent optical transition, called E_+ , detected by electro-reflectance measurements for the samples with nitrogen concentrations of $\geq 0.8\%$ [3, 4]. This peak is located at about 0.4-0.8 eV above the conduction band (CB) minimum (denoted as E_-) and shifts upward in energy with increase of nitrogen concentration [3, 4, 5].

Several physical mechanisms have been proposed to describe these nitrogen-induced changes : two-level band anticrossing (BAC) model [6, 7], disorder-allowed Γ -X-L coupling [8, 9], and the formation of the impurity band [10]. In the frames of the BAC model the E_+ state naturally appears as the high-energy solution of a two-state Hamiltonian, describing the interaction of the localized nitrogen state with the extended CB states of the host matrix compound [11]. However, the first-principles [8, 12, 13, 14] as well as empirical pseudopotential [9, 15, 16] calculations failed to validate the BAC model. On the other hand, based on these calculations, the intraband coupling model has been proposed. In this model the E_+ peak is caused by a disorder-allowed transition from the valence band (VB) maximum to the L -point of the conduction band. In particular, it was proposed that the energy position of the E_+ transition is a configuration-weighted average of a nitrogen impurity state and CB L -state, denoted as L_{1c} [9]. However, to our knowledge, there are no studies of the GaAsN system, which identify and clarify the origin of the E_+ transition based on direct first-principles calculations of the optical properties of this system.

In this Letter we report the results of theoretical study of the optical properties of GaAsN system using state-of-the-art *ab-initio* method based on density functional theory (DFT). The E_+ transition is identified by direct calculation of the dielectric function of the system for nitrogen concentrations of 0.9-3.7%. Its origin is further clarified by studying band-to-band contributions to the dielectric function. To understand the effects of atomic ordering, the supercells of different symmetry are constructed and studied separately. Our results show that the E_+ transition is formed by the interplay of two contributions : the Γ -point transitions to the L_{1c} -derived states of the GaAs matrix, and the L -point transitions to the impurity-modified first conduction band of the system. Further, we study the changes in these contributions, caused by different impurity distribution, and show the importance of nitrogen potential in the formation of the E_+ transition.

Our calculations were performed within the local density approximation (LDA) and generalized gradient approximation (GGA) to the density functional theory [17]. Four supercells were constructed to describe GaAs_{1-x}N_x system with nitrogen concentrations in the range of $x = 0.0093$ -0.037. In 64-atom and 216-atom supercells nitrogen atoms form a simple cubic (SC) lattice, while in 54-atom and 128-atom supercells a face-centered cubic (FCC) impurity sublattice is formed. A pseudopotential planewave method as implemented in ABINIT [18] code was employed for full geometry optimization of the supercells. This included structural relaxation both with respect to the volume of the unit cell and to the internal coordinates of the atoms. A 16 Ry basis cutoff and $2 \times 2 \times 2$ Monkhorst and Pack [19] sampling of the Brillouin zone (BZ) showed good results for structural relaxation. The LDA exchange-correlation functional of Perdew and Zunger [20] has been used for calculations.

Having obtained geometrical characteristics of the supercells, we proceeded further with a highly-accurate lin-

FIG. 1 – Calculated imaginary part of the dielectric function for $\text{GaAs}_{1-x}\text{N}_x$ systems, normalized per unit volume. A progressive Lorentzian smearing with full width at half maximum (FWHM) of $0.01(\hbar\omega)^2$ has been applied.

earized augmented plane wave method (LAPW) as implemented in WIEN2K program package [21]. This method belongs to the family of all-electron DFT-type methods and does not use any pseudopotentials. Band structures and optical properties of the model systems have been calculated using the GGA exchange-correlation functional of Engel and Vosko [22]. This functional significantly improves the values of the band gap and effective electron and hole masses for GaAs [23] as well as for GaAsN [24] systems. For calculation of optical properties a dense $20 \times 20 \times 20$ \mathbf{k} -grid has been used [25]. Having obtained selfconsistently the crystal wavefunctions $|\mathbf{k}n\rangle$ and band energies $E_{\mathbf{k}n}$ for n bands of the system, the imaginary part of the dielectric function $\varepsilon_2(\omega)$ can be calculated by summing direct transitions over the BZ, weighted with corresponding matrix element of the transition probability :

$$\varepsilon_2^{ii}(\omega) = \frac{Ve^2}{2\pi\hbar m^2\omega^2} \int d^3k \sum_{nn'} |\langle \mathbf{k}n | p_i | \mathbf{k}n' \rangle|^2 \times f_{\mathbf{k}n}(1 - f_{\mathbf{k}n'}) \delta(E_{\mathbf{k}n'} - E_{\mathbf{k}n} - \hbar\omega).$$

Here $\mathbf{p} = -i\hbar\nabla$ is the momentum operator, and $f_{\mathbf{k}n}$ is the Fermi distribution function, which ensures that only transitions from occupied to unoccupied states are included in summation.

We present in Fig.1 calculated imaginary part of the dielectric function (ε_2) for GaAsN systems with nitrogen concentrations of 0.93, 1.56, 3.13, and 3.70%. A calculated ε_2 for pure GaAs is also presented for sake of comparison. All main features, observed experimentally for GaAs and GaAsN systems, are well-reproduced by theoretical calculations. The common features of the dielectric function for the pure and doped systems include the presence of the fundamental absorption edge E_0 , as

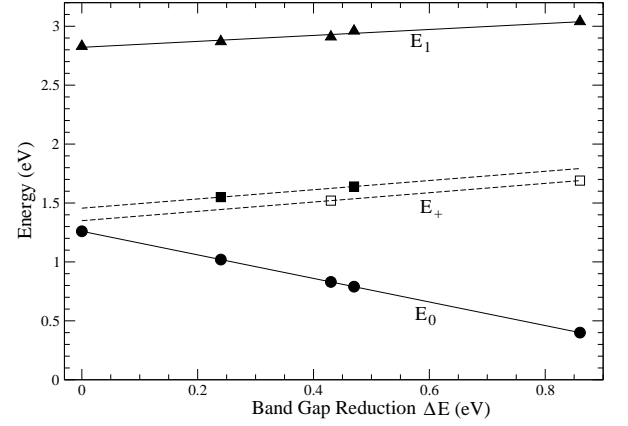

FIG. 2 – Optical transition energies vs band gap reduction : the E_0 , E_+ , and E_1 transitions are presented.

well as two main maxima, namely peaks E_1 and E_2 . The origin of these features is well-understood and described in the literature [26]. The fundamental absorption edge is due to transitions between valence band maximum and conduction band minimum, which occur in the center of the Brillouin zone. The E_1 peak is related to direct transitions along the eight equivalent $\Gamma - L$ directions of the BZ. And, finally, the absolute maximum E_2 contains contributions from the direct transitions occurring near X -point of the BZ.

It is clearly seen that with increase of nitrogen doping the fundamental edge moves down to lower energies. This reflects the effect of the nitrogen-caused band gap reduction, and agrees well with experimental observations [7, 24]. We also notice that the E_2 peak hardly moves with increase of the nitrogen contents, while the E_1 transition moves slightly to higher energies. The main feature, which makes the spectra of GaAs and GaAsN systems substantially different, is the appearance of a new nitrogen-induced peak, which we attribute to the E_+ transition, observed experimentally. With increase of nitrogen content the E_+ peak shifts to higher energies faster than the E_1 transition.

To represent our results quantitatively, we plot in Fig.2 the optical transition energies as a function of band gap reduction $E_0(\text{GaAs}) - E_0(\text{GaAsN})$ with the energies measured relative to the VB maximum. In this representation the E_0 transition is a straight line with a slope of -1.0. The energy evolution of the E_1 peak can also be well-approximated by a straight line with a slope of +0.25. This slope is close to +0.22, experimentally obtained by Shan *et al* [27] for four different nitrogen concentrations with further parametrization of the results within the BAC model.

While for E_0 , E_1 and E_2 the exact transition energies can be easily determined directly from the dielectric function, this task becomes much more difficult for the E_+

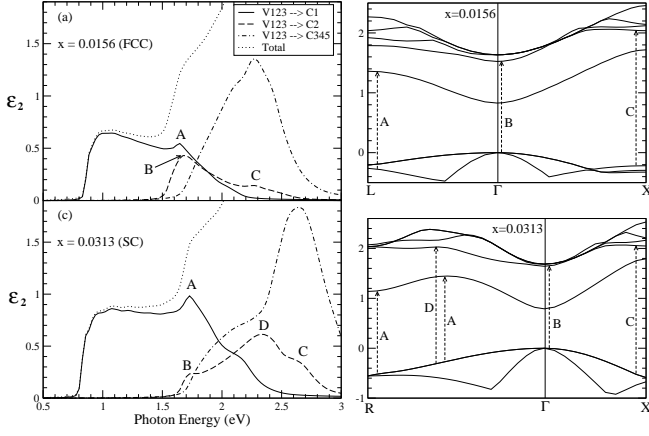

FIG. 3 – (a) and (c) : Contributions to the imaginary part of the dielectric function from different band combinations, calculated for 128- and 64- atom supercells. (b) and (d) : Calculated electronic bandstructure of these supercells showing the various direct transitions, responsible for the features in ε_2 .

peak. This transition is clearly visible only for 64- and 128- atom supercells. For the system with the highest nitrogen concentration of 3.7% this transition is smeared to large extent probably due to strong N-N interactions, while for the smallest concentration of 0.93% it is hardly visible due to a reduced oscillator strength. By comparing the dielectric function for 128- and 64- atom supercells with corresponding energy spectra at the Γ -point, we find that the E_+ transition energy for these structures exactly corresponds to the position of the $a_1(L_{1c})$ singlet. At this point we are making an important assumption, which will be later verified by a detailed analysis. We assume that for the other two structures the E_1 peak also originates from a Γ transition to the $a_1(L_{1c})$ singlet. This assumption is also supported by the fact that for our model system, containing 0.93% of nitrogen, this singlet is located at 0.53 eV above the conduction band minimum, which is in good agreement with experimental value of 0.57 eV, obtained for the E_+ peak for the samples with 1% of nitrogen [5].

Now we plot in Fig.2 the energies of the E_+ transitions within the same representation. Linear approximations, performed separately for SC- and FCC- types of supercells, showed practically the same slope of +0.40, which is smaller than experimental value of +0.67, obtained by Perkins *et al* [3] for the samples with four different nitrogen concentrations. Extrapolation to the dilute limit gives the average value of $E_+ - E_0(x = 0) = 145$ meV, which is close to the experimental interval of 150-180 meV, obtained for the energy position of nitrogen level in GaAs [16]. However, such a detailed comparison should be done with a caution due to the fact that only two points are available for each type of structures.

We now try to understand the origin of the E_+ transition in the $\text{GaAs}_{1-x}\text{N}_x$ system. The expression, used for the calculation of $\varepsilon_2(\omega)$, gives us a natural possibility to calculate the contributions to the dielectric function from different band combinations. Figure 3(a,c) represents this decomposition of ε_2 , performed for the systems with 1.56% and 3.13% of nitrogen, taking into consideration only three top valence and five lowest conduction bands. Only these combinations were found to be responsible for the formation of the dielectric function in the energy interval 0.0-2.5 eV, which includes the E_+ transition.

Let us first concentrate on the system with 1.56% of nitrogen (Fig. 3a). We consider three contributions to the dielectric function : transitions to the first conduction band (C_1), to the second conduction band (C_2), and cumulative transitions to the conduction bands 3, 4 and 5 (C_{345}). We observe that the transitions to C_{345} do not contribute to the near-edge features of ε_2 . The results show that the E_+ feature is formed by contributions of two transitions, marked A and B, which both are energetically located near 1.65 eV, but have completely different origin. Analyzing the energy positions of peaks A and B, and keeping in mind that they come from the transitions to different conduction bands C_1 and C_2 , we are able to uniquely connect these transitions with corresponding saddle points in the bandstructure of the system. Figure 3b represents the bandstructure of the 128-atom supercell, showing three top valence and five lowest conduction bands. The results show that the peak A is formed by the transitions from the the valence bands to the first conduction band near the L -point of the BZ, while the peak B is due to the transitions to the second conduction band near the Γ -point. The fact that these two transitions are very close in energy and have significant intensities, leads to the formation of a well-defined feature in the spectrum, which we attribute to be the E_+ transition. The transitions near the X -point of the BZ contribute to the spectrum in the form of the peak C. It is formed by the transitions to the second conduction band, but it is twice smaller than peak B in intensity, and is located at higher energies.

It was found that large configuration-induced bandgap fluctuations are present in the GaAsN systems both in cases of one-dimensional nitrogen chains [28], as well as at relatively low nitrogen concentrations [24]. It seems interesting to study the influence of impurity ordering on the formation of the E_+ transition. So, we proceed further with the same decomposition analysis of ε_2 for the 64-atom supercell, where the nitrogen atoms form a simple cubic sublattice. The contributions of the C_1 , C_2 and C_{345} bands are represented in Fig. 3c, and the band structure with corresponding optical transitions is shown in Fig. 3d. The results show that the E_+ transition is also formed by a combination of peaks A and B, but the relative intensities of these peaks change. Comparing Fig. 3a and Fig. 3c we observe that the contribution of

peak B decreases, while the one of peak A increases. The increase of the contribution of the band C_1 for the SC-type supercell can be explained by the appearance of the additional saddle point in the $\Gamma - R$ valley. The saddle point of the same type appears also in the C_2 band, which leads to the formation of additional peak D, which is not observed in the FCC-type structure.

We now conclude our study by exploring the role of impurity potential in the process of the formation of the E_+ transition. Besides splitting the L_{1c} -states into a singlet and a triplet, the introduction of nitrogen also leads to a strong perturbation of the first conduction band of the host compound [16]. These two effects could be caused by both the geometrical deformations near the impurity atom, and by the nitrogen potential itself. In this last part of our study we are making an attempt to verify the influence of these two effects on the formation of the E_+ transition.

To gain further insight we performed calculations of the electronic structure for two model systems with subsequent analysis of different contributions to the dielectric function. We have first taken the 128-atom supercell with the fully relaxed geometry and replaced nitrogen atom back to arsenic. Thus, in this model we have removed the effects of the impurity potential, staying only with the effects of structural relaxation. The results show two dramatical changes in the electronic structure and optical properties of the system : the band gap of this model structure opens to the value of 1.29 eV, which is close to 1.26 eV, obtained for the GaAs structure, and the E_+ transition is no longer present in the spectrum. The contribution analysis demonstrated the reduction of the amplitudes of peaks A and B to practically negligible values. Moreover, in spite of local geometrical deformations, the splitting of L_{1c} states is now only 0.06 eV, which is almost twice lower than 0.11 eV, observed for the N-doped supercell. This demonstrates that local mechanical deformations introduce only small perturbations to the GaAs system, which are not responsible neither for dramatic band gap reduction, nor for the appearance of the E_+ transition.

These conclusions are supported by our results, obtained for the second model structure. In this case we have taken the N-doped 128-atom supercell, but stayed within the geometry of the GaAs structure. This model allows us to observe only the effects of the nitrogen potential without any influence of impurity-caused deformations. The decomposition analysis showed that both peaks A and B, which are responsible for the formation of the E_+ transition, are present in the spectrum. The differences from the relaxed structure include the larger splitting of the L_{1c} states (0.17 eV) and shifts in the energy positions of peaks A and B. We also observe opening of the band gap up to 1.13 eV. However, this value is smaller than the one, obtained for the previous model system, where only the absence of the nitrogen potential

caused a dramatic opening of the band gap to the one of the GaAs structure.

In conclusion, we have presented theoretical study of the optical properties of the GaAsN system. The origin of the experimentally observed E_+ transition is identified by the analysis of the dielectric function, calculated *ab-initio* for four different supercells. Our results show that the main contribution to the E_+ peak is given by Γ -point transitions from the VB maximum to the $a_1(L_{1c})$ -singlet, which originates from a nitrogen-induced splitting of the CB L -point. At the same time, nitrogen-induced modifications of the first CB are found to give rise to additional L -point direct transitions. Being close in energy to Γ -point transitions, they are shown to contribute significantly to the formation of the E_+ peak. Finally, local geometrical deformations are found to be only a second order effect in the process of the formation of the E_+ transition, and the influence of the impurity potential itself is shown to be responsible for the E_+ transition and dramatic band gap reduction in GaAsN.
