We have measured temperature and magnetic field dependencies of the sound velocities and the sound attenuation in $\text{HoNi}_2\text{B}_2\text{C}$ single crystals. The main result is a huge softening the velocity of C_{66} mode due to a cooperative Jahn-Teller effect, resulting in a tetragonal-orthorhombic structural phase transition. Anomalies in the behavior of the C_{66} mode through various magnetic phase transitions permit us to revise the low temperature H-T phase diagrams of this compound.

PACS numbers: 62.20.Dc, 64.70.Kb, 71.70Ej

Holmium borocarbide $\text{HoNi}_2\text{B}_2\text{C}$ is one of the most interesting members of the rare earth borocarbide family. The list of phenomena that have been found in this compound at low temperatures contains many of the mainstream research issues of solid state physics. Among them are the coexistence of superconductivity and magnetism, occurrence of multiple magnetic phases, including incommensurate spiral structures, and reentrant superconductivity (see¹ for a review). In this paper we uncover one more facet of complexity of $\text{HoNi}_2\text{B}_2\text{C}$: the presence of strong Jahn-Teller interactions.

Over the past decade almost all of the available arsenal of experimental tools has been used in the studies of borocarbitides. However it seems that ultrasound methods did not receive the proper attention, and as a result the acoustic properties of these compounds are mostly “terra incognita” at present. In this work we have performed acoustic investigation of $\text{HoNi}_2\text{B}_2\text{C}$ single crystals and obtained valuable data that are complementary to the known results. In particular, we have discovered a considerable softening of the C_{66} elastic modulus that starts at temperatures as high as 100K. This is indicative of the strong Jahn-Teller interaction present in this compound. This interaction is the driving force of the tetragonal-orthorhombic structural phase transition². The magnetic phase transitions are accompanied by elastic anomalies which are most pronounced for the C_{66} mode. By analyzing these features we were able to construct the H-T phase diagrams that added a few details to the existing phase diagrams (see for example³).

Single crystals of $\text{HoNi}_2\text{B}_2\text{C}$ were produced using the method described previously⁴. Samples had the shape of plates of 0.2 mm thickness. The c axis of the crystal was oriented perpendicular to the surface of the plate. The technique of working with submillimeter samples and the method of phase measurements are presented elsewhere⁵. The characteristic feature of the method is the utilization of an electronically controlled phase shifter with a dynamical range that is practically unlimited. This, along with the use of a digital phase measuring device, allows to keep a very high resolution for large changes in the sound velocity. While the behavior of all pure modes

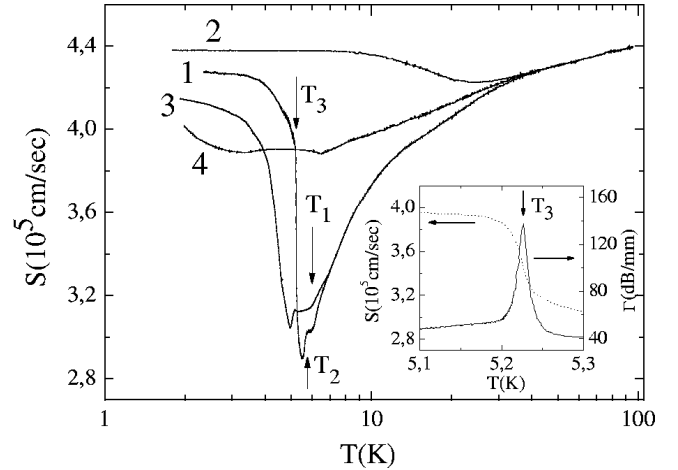

FIG. 1: Temperature dependence of the velocity of the C_{66} mode. Curve 1: $H = 0$, curves 2, 3 and 4: $H = 4T$ oriented along [110], [001] and [100] correspondingly. Arrows indicate the anomalies for $H = 0$. Insert: the attenuation (full line, right axis) and velocity (dotted line, left axis) of the C_{66} mode near 5.2K for $H = 0$.

of the crystal have been studied, we devote this paper mainly to the analysis of the most informative C_{66} mode. The anomalies of the sound velocity of the C_{44} mode are also briefly discussed at the end.

Shown in Fig. 1 are the temperature dependences of the sound velocity, S , of the C_{66} mode both in the absence of an external magnetic field H and when the field is oriented along main crystal directions. For $H = 0$ (curve 1) S exhibits a considerable, about 35%, softening that starts showing up long before the onset of magnetic ordering found at $T \sim 10\text{K}$ by neutron diffraction experiments^{2,6}. At $T_{cr} = 5.23\text{K}$ there is a return to a stiffer state marked by a jump in S . If a magnetic field of $H = 4T$ is applied in the basal plane (curves 2 and 4) the magnitude of the softening is strongly reduced, though not eliminated completely. On the other hand, S is affected very little if the field is applied along the c axis (curve 3).

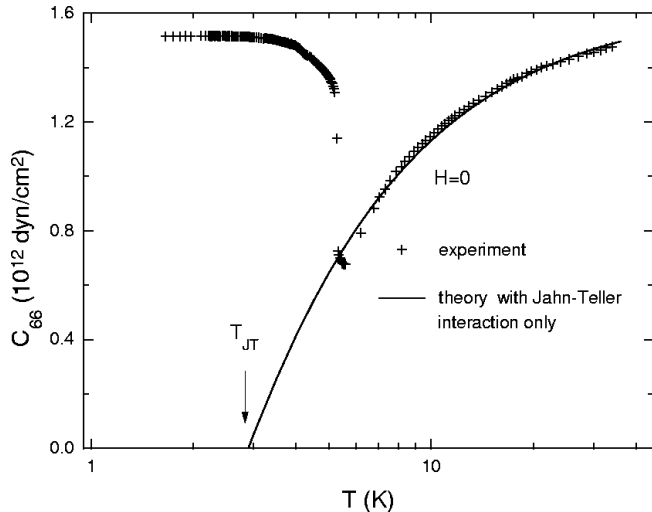

FIG. 2: Temperature dependence of the C_{66} elastic modulus for $H = 0$. Crosses are the experimental points, solid line is the theoretical result.

A wide temperature interval in which a softening of elastic constants takes place is the fingerprint of the Jahn–Teller interaction⁷. The elastic constant of the lattice itself (background elastic constant $C^{(0)}$) increases very slowly with decreasing temperature. Much stronger temperature dependence comes from partially filled inner electronic shells of rare earth ions. For $HoNi_2B_2C$ the crystal field splitting of the lowest J–multiplet of Ho^{3+} ion is about 200K⁸, which explains why we do not see the pure background elasticity even at the highest temperatures used in our experiments (about 100K). The localized electronic degrees of freedom are coupled to an extended degrees of freedom associated with the lattice. The elastic modulus of interest can be calculated as follows (see, for example⁷):

$$C_{66} = C_{66}^{(0)} - \frac{T}{v_{cell}} \frac{d^2}{d\varepsilon_6^2} \left[\log \sum_i \exp \left(\frac{-E_i(\varepsilon_6)}{T} \right) \right]_{\varepsilon_6=0}$$

where v_{cell} is the unit cell volume and E_i are the eigenvalues of the single ion Hamiltonian $H_{ion} = V_{CF} + V_{JT}$ which operates within the lowest multiplet of Ho^{3+} ion with $J=8$. The crystal field Hamiltonian V_{CF} has the form standard for tetragonal symmetry with the parameters determined by Gasser *et al.*⁸ The magnetic-ion–lattice (Jahn–Teller) interaction is taken in the simplest form $V_{JT} = -g\varepsilon_6 O_2^{-2}$, where $\varepsilon_6 \equiv \varepsilon_{xy}$ is the relevant component of the strain tensor and O_2^{-2} is the lowest order electronic quadrupole operator to which this strain couples by symmetry. Both $C_{66}^{(0)}$, assumed temperature independent, and the unknown coupling constant g were determined from a fitting procedure in the temperature range where the system is paramagnetic. In Fig. 2 we show and the best fit (solid line), which corresponds to $g = 2.24$ meV/ion and $C_{66}^{(0)} = 1.63 \times 10^{12}$ dyn/cm², along with the experimental points (crosses) for $H = 0$. The

agreement is quite good. The steep increase of $C_{66}(T)$ at $T_{cr} = 5.23K$ is due to interactions with magnetic degrees of freedom, which we do not attempt to account for in this work.

The next conclusion is that Jahn–Teller interaction is in fact quite strong. If there were no other interactions in the system the crystal lattice would become unstable at about $T_{JT} = 2.89K$ as indicated by the vanishing of the calculated C_{66} (see Fig. 2). Therefore, the Jahn–Teller interaction is the driving force of the structural phase transition from the tetragonal to orthorhombic phase that most probably takes place simultaneously with the stabilization of collinear antiferromagnetic ordering at $T_{cr} = 5.23K$. Orthorhombic distortions of the crystal lattice have been observed previously at about 2K² and were associated with the magnetostriction.

FIG. 3: Phase $H - T$ diagrams for $H||[100]$ (top panel) and $H||[110]$ (bottom panel). Points belonging to different branches are denoted by symbols of different shape; lines are guidance for eyes. Full symbols – results of T -sweeps with fixed H , open symbols – results of H -sweeps with fixed T .

Neither the sound velocity nor the sound attenuation, Γ , develop any visible anomalies at the superconducting phase transition ($T_c \simeq 8K^1$) in our experiments. At the same time magnetic phase transformations can be detected quite easily with the behavior of the C_{66} mode. The typical shapes of the anomalies in the sound velocity and the sound attenuation are clearly seen in Fig. 1. The characteristic features are different for different phase transformations. For the sound velocity there is a change in the slope (jump in the derivative) at temperatures T_1 , while at T_2 there is a jump-like decrease and at T_3 there is a jump-like increase. Usually, these kinds of anomalies in the sound velocity are accompanied by an increase of the sound attenuation, which can be quite large in some cases (for example at T_3 , see the insert in Fig. 1). In principle, by the type of anomaly one can determine the nature of the corresponding phase transformation. For instance, the change in slope of the

sound velocity at T_1 corresponds to a second order phase transition of the improper segnetoelastic type.

Leaving such an analysis for a future publication we present in Fig. 3 the obtained $H - T$ phase diagrams for $H||[100]$ (top panel) and $H||[110]$ (bottom panel). Note that we used two types of measurements: temperature sweeps with fixed magnetic field and field sweeps with fixed temperature. In all cases the external parameter was kept increasing during sets of sweeps.

FIG. 4: Temperature dependence of the attenuation (full lines, right axis) and velocity (dotted lines, left axis) of the C_{66} mode for a) $H(0.45T)||[100]$, b) $H(0.6T)||[110]$ and c) $H(3T)||[001]$.

Let us discuss the case of $H||[100]$ (see Fig. 3, top panel) in more detail. At $H = 0$ the temperatures of the magnetic phase transitions practically coincide with those found in the literature¹. The location of line 1 is close to that of the other published data as well. Line 3 represents the position of a jump-like increase of the sound velocity, which is steep at $H = 0$ but smears considerably as H grows. The attenuation always goes through a maximum on line 3 (see insert on Fig. 1). At $H \simeq 0.4T$ line 3 splits forming a critical point. Shown in Fig. 4a are the $S(T)$ and $\Gamma(T)$ curves at $H = 0.45T$ where the splitting of the line 3 is obvious. In the literature lines 3 and 3b are associated with the boundary of a commensurate antiferromagnetic phase. Both line 3a

and line 3b represent an increase of the sound velocity in the form of a smeared step. They are possibly better detected as peaks in the attenuation (see Fig. 4a, right vertical axis). Although it is in principle possible that lines 3b and 3b stay separate from each other as the magnetic field decreases all the way down to zero, we were not able to observe any indications of such behavior. Line 3 is not split as $H \rightarrow 0$ within the accuracy of our experiments (see insert in Fig. 1).

FIG. 5: Magnetic field dependence of the attenuation (full lines, right axis) and velocity (dotted lines, left axis) of the C_{66} mode at $T = 5K$ for $H||[100]$.

The anomaly represented by line 2 is a step-like decrease of the sound velocity. At $H||[100]$ line 2 approaches line 3a as field increases, but disappears further on. Over some range of magnetic fields line 2 coexists with lines 3a and 3b (see Fig. 3, top panel). This is demonstrated in Fig 4a where all three peaks in the attenuation Γ are clearly distinguishable. The simultaneous presence of all these three anomalies can also be observed on an appropriate vertical cut of the $H - T$ plane in the top panel of Fig. 3. The magnetic field dependence of S and Γ at $T = 5K$, shown in Fig 5, confirms the coexistence of lines 2, 3a and 3b unambiguously.

In general, similar systematics holds true for $H||[110]$ as well (see Fig. 3, bottom panel). However, in the fields larger than the value at which lines 2 and 3a merge one can see a new feature on $S(T)$ and $\Gamma(T)$ curves (look up T_4 in Fig. 4b). This suggests the existence of one more line, line 4 in the bottom panel of Fig. 3, which could in fact be a continuation of line 2.

For $H||[001]$ the $H - T$ phase diagram essentially coincides with the one published in the literature¹. We do not present it again in this paper, but comment that in high fields line 3 is possibly split as well. Indeed, in fields as high as 3T (see Fig. 4c), we can readily define T_{3a} and T_{3b} on the attenuation temperature dependence curve, $\Gamma(T)$.

Fig. 6 shows the temperature dependences of the velocity of the C_{44} mode in both Ho and Y borocarbides that also exhibits slight softening. Notice that the mag-

FIG. 6: Comparison of the temperature dependence of the C_{44} mode velocity for YNi_2B_2C (top panel; $q||[001]$, $H||[001]$) and $HoNi_2B_2C$ (bottom panel; $q||[001]$, $H||[100]$).

nitude of the effect for this mode is three orders of magnitude smaller than for the C_{66} mode in the Ho compound (see Fig. 1). The Y^{3+} ions in the other compound have all electronic shells completely filled, and therefore do not couple to the lattice by means of the mechanism discussed above. A softening of the C_{44} mode velocity in YNi_2B_2C for $H = 0$ has been observed recently by Isida *et al*⁹ who associated it with the presence of a nesting

feature of the Fermi surface.

Such anomalies have attracted a lot of attention in the 1970s in connection with superconductors of the A-15 crystal structure as a possible source of low temperature structural transformations¹⁰. The theory¹¹ predicts a logarithmic dependence of the active elastic modulus on temperature (for a given geometry). This is satisfied reasonably well for both compounds (see Fig. 6), providing the evidence of a measurable coupling of itinerant electrons to the lattice. In borocarbides this coupling is much weaker than in A-15 compounds, which could be due to a smaller contribution of 1D bands to the electronic spectrum.

Apart from a similar temperature dependence in the range of temperatures where softening takes place, the behavior of the C_{44} elastic modulus in Y and Ho borocarbides with further decrease of temperature is very different. In the former compound the lattice softening stops upon stabilization of the superconducting phase, including the mixed state in magnetic fields (Fig. 6, top panel). In the latter compound the lattice starts growing stiffer only after magnetic ordering occurs while the onset of superconductivity does not produce any visible effect.

In summary, we demonstrated the presence of a Jahn–Teller interaction in $HoNi_2B_2C$ which is sufficiently strong to make the high temperature tetragonal crystal structure unstable (a cooperative Jahn–Teller effect). The details of $H - T$ phase diagram were clarified. We presented evidence in favor of the existence of critical points where several phase transition lines merge or perhaps intersect.

This study was supported in part by CRDF Foundation (Grant UP1-2566-KN-03). The work of AK was supported by the Natural Science and Engineering Research Council of Canada (NSERC) and the Canadian Institute for Advanced Research (CIAR).
