(Dated: April 14, 2024)

N eutron scattering investigations were carried out in PbM $g_{1=3}Ta_{2=3}O_3$ and B aM $g_{1=3}Ta_{2=3}O_3$ complex perovskites. The crystal structure of both compounds does not show any phase transition in the tem perature range 1.5 { 730 K.W hereas the tem perature dependence of the lattice parameter of B aM $g_{1=3}Ta_{2=3}O_3$ follows the classical expectations, the lattice parameter of relaxor ferroelectric PbM $g_{1=3}Ta_{2=3}O_3$ exhibits anom alies. O ne of these anom alies is observed in the same tem perature range as the peak in the dielectric susceptibility. We nd that in PbM $g_{1=3}Ta_{2=3}O_3$, lead ions are displaced from the ideal positions in the perovskite structure at all tem peratures. Consequently short-range order is present. This induces strong di use scattering with an anisotropic shape in wavevector space. The tem perature dependences of the di use neutron scattering intensity and of the am plitude of the lead displacements are sim ilar.

I. IN TRODUCTION

Since com plex $AB_x^0B_{1x}^0O_3$ perovskites have two different ions in the B-sublattice, their properties are richer than the ones found in the classic ABO_3 counterparts¹. In particular, there is a subgroup of com plex perovskites, relaxor ferroelectrics, which exhibit an anomaly in the dielectric susceptibility, broad in temperature and also frequency dependent. Unlike in usual ferroelectrics this anomaly does not link to macroscopic structural changes¹,². Despite num erous studies, a coherent understanding of relaxor ferroelectrics is still lacking¹,²,^{3,4,5}.

 $P\,bM\,\,g_{1=3}N\,b_{2=3}O_3$ (PMN) crystal is a model system to study relaxor behaviour^{1,2,6}. The real part of the dielectric permeability "⁰ of PMN has a maximum at 270 K and frequency = 10 kH z^{1} . The average Т crystal structure of PMN is cubic down to 5 K⁷. How – ever, an applied electric eld induces a structural phase transition at T 210 K⁸. PbM $g_{1=3}Ta_{2=3}O_3$ (PM T) is a well-known ferroelectric and it was among the rst studied relaxors¹. The average structure is cubic in the range of exam ined tem peratures and external electric elds^{1,9}. In PMT, the real part of the dielectric susceptibility at = 10 kHz has a maximum at T 170 K, i.e. considerably lower than in other important relaxor crystals like PMN and $PbZn_{1=3}Nb_{2=3}O_3$ (PZN)¹. This suggests that tem perature-induced anharm onicity less affects the properties of PM T in the range of the dielectric anomaly. Consequently, PMT can be considered as the simplest relaxor system known. Thus, understanding the physical mechanisms underlying the relaxor properties in a PMT crystal should be easier than in the related compounds. Unfortunately, PMT was studied much less then PMN and PZN. It is only recently that

studies of PM T by X-ray di raction^{9,10}, neutron scattering^{11,12,13,14}, light scattering^{12,15} and calorim etry¹⁶ were carried out. On the other hand, low-dielectric permeability is found in m any Ba and Sr-based com plex perovskites¹⁷. BaM $g_{1=3}Ta_{2=3}O_3$ (BM T) is an exam ple of such a material¹⁸. In spite of chem ical disorder in the B-sublattice, BM T does not exhibit any lattice instability or relaxor-like dielectric anom aly^{11,12,15,19}. Note also that exchanging lead in PM T with barium in BM T suppresses the relaxor properties of the form ercrystal. Thus, com paring the properties of PM T and BM T m ight be extrem ely instructive.

In this paper, we present results of neutron scattering studies in PMT and BMT in the tem perature range 1.5 K < T < 730 K, that covers the dielectric m axim um 1 as well as the anom alies observed in the velocity and in the dam ping of the longitudinal acoustic phonon¹⁵ in PM T. In Section II, we describe the experimental procedure. Section III starts with the explanation of the di erent m odels used for the crystal structure re nem ent of PM T and BM T and contains a discussion of the di use scattering m easurem ents in PM T. Further, in x IIIC, we present the tem perature dependences of the lattice param eters of both BMT and PMT. In x IVA, we describe the evolution of the tem perature factors and show that there is a pronounced correlation between the di use scattering intensity and the Pb displacem ents in PM T. In x IV B we propose a possible approach to describe DS in relaxors. Finally, in x IV C we compare the temperature dependences of the lattice parameter of PMT and PMN.

II. EXPERIMENTAL

The synthesis of the pow der sam ples was described previously¹¹. The mass of each sam ple was about 15 gram s. The single crystal of PM T used in the present study was grown by the Czochralskim ethod and has a size 6.5 4.5 1.6 mm³. The same crystal was used in previous dielectric, light and neutron scattering studies^{13,15}.

Them easurem entswere perform ed at the neutron spallation source SINQ (PSI, Switzerland). The powder di raction data were taken the the multi-detector highresolution powder di ractom eter HRPT²⁰. The polycrystalline samples of PMT and BMT were placed into cylindrical containers with 10 mm diameter and 50 mm height. M easurem ents were perform ed with the neutron w avelength = 1:1545 A. This set-up gives access to more then 40 unique Bragg re ections in the range of scattering angles 7° { 164.5°. A typical exposure time 20 m inutes, but at few tem peratures the expowas sure time was increased to 4 hours. The program Fullprof²¹ was used for crystal structure renement using the R ietveld m ethod. The neutron scattering m easurem ents on a single crystal of PMT were performed at the cold neutron three-axis spectrom eter TASP²². The (002) reection of pyrolytic graphite (PG) was used to m on och rom ate and analyze the incident and scattered neutron beam s. The PG monochrom ator was vertically curved and a PG lterplaced in the incom ing neutron beam was used to suppress contam ination from higher-order neutron wavelengths. The spectrom eter was operated in the elastic m ode with the neutron wavevector $k_i = 1.97$ A 1 . The horizontal collimation was quide 80° 80° . The sample was mounted on an alum inum holder with the (h h 0) and (0 0 1) Bragg re ections in the scattering plane.

III. RESULTS

A. Structure Re nem ent

Figure 1 shows the observed and calculated di raction patterns obtained for BM T at T = 580 K. For the re nem ents, the chem ical composition of B aM $g_{1=3}Ta_{2=3}O_3$ was xed at the stoichiom etric values. Random occupation of the Mg/Ta ions over the B-sites of BMT perovskite structure was assumed. In a rst approach, we used anisotropic temperature factors for oxygen. It turned out, however, that within the statistical errors, the ratio $_{11} = _{33}$ 1 was constant even at high tem peratures. Hence, for the subsequent re nem ents, the tem perature factors were supposed to be isotropic. The crystal structure was found to be consistent with Pm 3m space group, where barium is located at $(0\ 0\ 0)$, oxygen is at $(0.5\ 0.5\ 0)$, and M g/Ta ions are statistically distributed over the (0.5 0.50.5) position. At T = 580 K there nem ent procedure yielded a lattice constant a = 4.10289 (8) A and tem perature factors B_{iso} (Ba) = 0.86(2) A^2 , B_{iso} (O) = 1.09(1) A^2 ,

 B_{iso} (M g=Ta) = 0:60(1)A². This model gives a precise description of the experimental data ($^2 = 2.52$; $R_p =$ 3:49; $R_{wp} = 4:44$; $R_{Bragg} = 3:57$) and was used to rene neutron diraction patterns at other temperatures. We note that, despite a general tendency toward hexagonal ordering in Ba-containing complex perovskites^{17,18}, the synthesism ethod described in Ref.¹¹ produces cubic perovskites with ionic disorder in the B-site.

FIG.1: Neutron powder di raction pattern of BMT collected at T = 580 K. Observed data points, calculated pro le and di erence curve are show n. The two rows of ticks correspond to the calculated positions of di raction peaks for BMT (upper) and M qO im purity (3%).

Figure 2 shows the diraction pattern obtained for PMT at T = 588 K and treated with the Rietveld m ethod. Dierent hypotheses for the structural model of PMT were tested during the renem ent procedure. As in BMT, the cubic perovskite structure (space group Pm 3m) was assumed as a starting model. In this model, the rened values of the isotropic therm al parameters for lead and oxygen were found to be very high with B_{iso} (Pb) = 4:08 (3)A² and B_{iso} (0) = 1:73 (1)A², respectively. These values are much higher then those found for B_{iso} (M g=Ta) = 0.58 (7) A², and for the isotropic tem perature factors in the reference compound BMT. In particular, the large value of B iso (Pb) is anom alous and indicates a possible structural disorder. A sim ilar situation was observed before in many lead-based complex perovskites like PMN²³, PMN+ 10% PT (PMN-PT)²⁴, $PbSc_{1=2}Nb_{1=2}O_{3}^{25}$, and also in $PbFe_{1=2}Nb_{1=2}O_{3}^{26}$ (the list is far from complete). In all these examples, Pb was never found to be located exactly at the 1a (0 0 0) W ycko position. Thus, to improve our structuralm odel, both displacements of Pb from the 1a (000) special Wycko position and an isotropic tem perature factors for oxygen ions were introduced. We considered the shifts of Pb

FIG.2: Neutron powder di raction pattern of PMT collected at T = 588 K. Observed data points, calculated pro le and di erence curve are show n. The two rows of ticks correspond to the calculated positions of di raction peaks for perovskite PMT (upper) and pyrochlore in purity (5 %).

At 588 K the values for the Pb-shifts together with the reliability factors R_{B ragg} are tabulated in Table I. Reliability factors for Pb-shifts along the < 001> direction are signi cantly worse than the corresponding value for the <110> and <111> directions. For the latter two directions, the quality of t is nearly the same at all tem peratures. Displacing Pb along <110> always gives a slightly better reliability factor and m in im izes the value of the isotropic tem perature factor of Pb. How ever, we do not put a strict physical sense in the choice of this particular direction for Pb-shifts. Namely, as was pointed out in Ref.²⁷, a preferable direction of the Pb-shifts can be arti cialbecause of insu ciently high values in (sin)= (note that we reached (sin m_{ax}) = 0.86 A 1). To our opinion, the quality of renement for the di erent displacem ent directions depends on the associated degeneracies: six-fold for the < 001>, eight-fold for < 111> and twelve-fold for < 110>. The latter direction of shifts gives the closest approximation of a sphere. Hence, we used the <110> direction to re ne the data taken at other tem peratures.

To improve the structural model further, we introduced shifts for M g/Ta ions and non-stoichiom etric values for Pb and O content. However, the t procedure converged to the nom inal stoichiom etric ratio. The introduction of shifts for M g/Ta, while keeping all other param eters xed, did not allow us to improve the structural model noticeably. Therefore, in the subsequent re nements, these parameters were xed at their nom inal values. The structural parameters obtained from the powder re nement at T = 588 K are given in Table II. We ob-

serve that on the contrary to BM T, the therm alellipsoid for oxygen is anisotropic ($_{11}=_{33}$ 3:44). We note also that despite introduction of displacements, the isotropic temperature factor for Pb is still quite in portant (see Table I), being 2.5 times larger than B_{iso} (M g/Ta) and 2 times larger than B_{iso} (Ba) in BM T.

B. Diuse scattering

In the following, we discuss the in uence of the diffuse scattering (DS) present on the powder di raction pattern of PMT.A lready in the earliest studies of PMN by X-rays²³ and neutron²⁸ di raction, di use scattering was found, the intensity of which grows as the tem perature decreases²⁸. M oreover, at low tem peratures, D S is so strong that it becomes observable even in powder di raction patterns²³. Later work on PMN single crystals showed that the distribution of di use scattering is anisotropic in reciprocal space^{29,30,31,32,33}. We have investigated the distribution of DS intensity in a single crystalofPMT at T = 140 K in the vicinity of the (110) and (0 0 1) Bragg positions. As shown in Fig. 3, the DS measured in the vicinity of (1 1 0) Bragg peak of PM T has a "butter y" shape in reciprocal space sim ilar to the DS observed in single crystals of PMN³⁰. Note, that the intensity of DS is mainly concentrated along the equatorial section transverse to the < 110> direction. M easurements in PMT around the (0 0 1) Bragg peak give a very sim ilar shape of DS. In that case, the most intense part of di use scattering is concentrated along the equatorial section transverse to the <001> direction. It is obvious that the q-dependence of DS in PMT is complicated and to incorporate properly the DS into the structuralm odel for pow der re nem ent is an extrem ely di cult problem. Hence, the DS occurring in the pow der di raction pattern was treated as background.

FIG.3: Surface of neutron di use scattering intensity around the (110) B ragg peak of PM T at T = $140 \text{ K} \cdot \text{N}$ ote that the intensity is given in a logarithm ic scale.

C . Tem perature dependence of the lattice parameters of PM T and BM T

Figure 4 shows that the tem peratures dependences of the lattice parameters for BMT and PMT are qualitatively dierent. Starting from high temperature, the lattice parameter of BMT decreases almost linearly as the tem perature decreases down to T 200 K. There is a cross-over regime between this temperature and Т 30 K, below which the lattice parameter of BM T is approxim ately constant. The tem perature dependence of the lattice parameter of BMT can be described by a quadratic polynom $a_0 + a_{01} T + a_{02}$ T^2 , where $a_0 = 4:08275(8)A$, $a_{01} = 1:77(1)$ $10^5 A$ K¹ and $a_{02} = 2:6(1)$ 10⁸ A K². Sim ilar tem perature dependences are commonly observed in solids (see for instance^{34,35} and references therein) and do not contain any signature of anom alies. This simply relects that in a broad tem perature range (1.5 K { 730 K), the lattice of BMT continuously expands. Hence, it appears that the presence of chem ical disorder on the B-sublattice does not a ect signi cantly the therm alexpansion of the BM T lattice.

The variation of the lattice parameters of PM T can be separated into three distinct tem perature regimes. As in BM T, the lattice parameter decreases linearly from high

FIG. 4: Tem perature dependence of the lattice parameters of PM T and BM T. The solid lines show the results of linear extrapolation for the a(T) dependence of PM T. The dashed line shows the polynomial t of a(T) for BM T. The insert shows the dependence of the lattice parameter of PM T in the region of tem peratures around T 180 K. Invar-like behaviour of PM T for T < 180 K is obvious.

tem peratures (da (T)=dT = $3:8923 \quad 10^5$ A K¹T) with a cross-over regime between T = 420 K and T 180 K.Bebw this tem perature, the lattice does not contract any m ore (da (T)=dT = $8:8 \quad 10^7$ A K¹). On the contrary to w hat is observed for BM T, a quadratic polynom does not reproduce the data shown in Fig. 4 and it is necessary to include powers up to 6 to describe the tem perature dependence of the lattice parameter of PM T. It is clear that such a behaviour is anom abus. We rem ind the reader that the peak in the dielectric susceptibility of PM T appears around T 180 K^{1,9}. Thus, the dielectric anom aly and the invar-like property in PM T are observed at the same tem perature (see Insert of Fig. 4).

IV. DISCUSSION

A. Correlation between the di use scattering intensity and Pb displacements in PM T

We turn now to the description of the temperature dependence of the amplitude of Pb displacements ($Pb_{<XX0>}$) and of the DS intensity in PMT shown in Fig.5.We measured the temperature dependence of the DS in PMT single crystal along [1,1,q]. In that direction, we nd that the line-shape can be reproduced using a Lorentzian function¹³:

S (q) =
$$\frac{I_0}{2} \frac{(q - q_0)^2 + q_0^2}{(q - q_0)^2 + q_0^2}$$
; (1)

where I_0 is the integrated intensity, is the full width at half maximum (FW HM), and q_0 determines the center of the Lorentzian. Note that this approximation was used in Ref.³² to analyze the intensity of DS in PMN.We monitored the evolution of DS in PMT in the temperature range 1.5 K { 375 K. At higher temperatures, the DS is extremely weak in intensity and broad in q-space, and the results obtained above T 400K cannot be analyzed reliably.

FIG.5: Tem perature dependences of the integrated intensity of di use scattering (DS) (black symbols) and am plitude of the Pb displacements (Pb $_{< X X O>}$) (open symbols) in PM T.

Figure 5 shows the tem perature behaviour of the integrated intensity of DS and of the re ned values of the $Pb_{\langle X X 0 \rangle}$ shifts in the temperature range 1:5 412K . Note that the values of the $Pb_{<XXO>}$ were derived from intensities of the Bragg peaks in the powder di raction patterns whereas DS was extracted from the broad intensity distribution around these Bragg peaks i.e. from short-range correlations. The correlation length extracted from the FW HM of the DS line shape is found to increase continuously with decreasing temperature and was published previously¹³. There is a pronounced sim ilarity between the increase of DS intensity and the displacem ent am plitude of Pb< X X 0> as the tem perature decreases. In the temperature range 1:5 K 90 K both quantities are constant within statistical errors and decrease monotonously as the tem perature is further increased. Finally, they tend to saturate above T 300 K although a very slow decrease of $Pb_{\langle X X 0 \rangle}$ above 412 K is not shown in Fig.5 for better com parison with the DS intensity. The results shown in Fig. 5 strongly suggest that lead displacem entsm ay be responsible for the occurrence of DS in PMT. There is how ever no linear relationship between the tem perature dependence of $Pb_{\langle X X 0 \rangle}$ and DS:while the DS intensity decreases by a factor of 30 when the tem perature increases from 1.5 K to 375 K, the change in $Pb_{\langle X X 0 \rangle}$ is of the order of 20% only. At higher tem peratures, lead displacem ents are still im portant, the DS is broad in q-space, since the correlation length is short¹³. In other words, while P b displacem ents are nearly uncorrelated or uncorrelated the DS is weak (or totally absent). With decreasing temperature the

Pb displacements increase and become correlated, which causes the appearance of the DS. Note also, that one cannot claim that only Pb displacements are responsible for DS. However, it was possible to satisfactorily t the di raction patterns of PMT assuming that only lead ions are displaced. This suggests that the main contribution to the DS in relaxor crystals originates from Pb ions. The recent observation of a temperature-dependent relaxation mode, coexisting with the central peak in PMN crystal³⁶, also supports this hypothesis.

B. Possible description of the DS

We discuss now the resemblance observed for the tem perature dependence of DS intensity and for Pb<XXO> . It seems that the q-dependence of DS in all relaxors, which have been studied so far, is very sim ilar. For example, DS with a "Butter y-like" shape is observed in PM N $^{\rm 32,33}$ and in PZN + 8% PbT iO $_3$ ³⁷. Furtherm ore, the intensity of DS is found to increase with decreasing tem perature in PMN 24,28,32 and PZN 38,39 , as here for PMT.From neutron and X-ray di raction data, it is known that there is a general tendency that Pb displacem ents increase as the tem perature decreases in complex perovskites (see $e.q.^{7,25,27}$). One can expect that the observed correlation between the DS intensity and the amplitudes of Pb displacements in PMT may help to create a model which describes short-range order in relaxors. In that vein, the calculations of K assan-O gly and N aish predicting an increase of di use scattering with decreasing tem perature due to change in ionic-oscillation amplitudes may be considered as a useful starting point⁴⁰.

C. Lattice expansion

High-resolution neutron di raction allowed us to study the tem perature dependence of the lattice constant a in PMT from 41 unique Bragg re ections in the tem perature range 1:5 K 730 K with tem perature step of 10 K. W e found changes of slope in a (T) at 420 K and 180 K which do not strictly agree with previous

tem perature studies of the lattice parameters in PMT. In Ref., an anomaly was observed rstatT = 573 K and the lattice parameters were found to remain constant below T = 280 K . W e ascribe the discrepancy between our data and those by Lu et al.⁹ to the facts that, rst, the latter m easurem ents were carried out using three B ragg peaks of low M iller indices and, second, the number of tem perature points was much reduced as compared to the present study. Thus, to our opinion there is no anom aly in the lattice parameter of PMT which could be directly connected with the Burns temperature T_d 570 K⁴¹. Interestingly, the change of slope of a (T) in PM T at high tem peratures occurs at tem peratures where we are able rst to observe the di use scattering. In other words, deviation from linear law in a (T) of PMT crystal appears when the shifts of Pb ions become correlated. Note, that the so-called "excess" specic heat in PMT also appears at T 420 K^{16} .

It is useful to compare the behaviour of the lattice parameters of PMT and PMN^{7,24,46} in the temperature ranges where dielectric anom alies are observed. In the rst neutron measurements by Husson et al.7, the lattice parameter of PMN was observed to remain roughly 300 K. However, recent studies constant below T have revealed a more complicated behaviour of a (T) in PMN. In Refs.^{24,46} a change of slope in a (T) was found 350 K and at T 200 K . In the tem perature at T range 200 { 350 K, D khil et al.24 reported a freezing of the lattice param eters, sim ilar to what we found in PM T 180 K. An important qualitative di erence in below the behaviors of the lattice param eters of PMN and PMT is that below T 200 K, a (T) for PMN decreases again as the tem perature is low ered, whereas for PMT such a change of regime is absent. We rem ind that at T 210 K PMN has an additional phase transition in an applied electric eld⁸. How ever, even without application of an external electric eld, properties like dam ping of longitudinal acoustic phonons⁴⁴, and the width of quasielastic component in light scattering spectra⁴⁵ exhibit anom alies in PMN in the vicinity of this tem perature. Thus, it is possible that this lattice instability is linked with the additional change of a (T) of PMN as the tem perature decreases below 200 K .

In the following we discuss possible causes for the anom abustem perature dependence of the lattice param – eter in PM T.As it is well-known (see for instance⁴⁷), the unit cell volum eV depends on tem perature T as

$$\frac{\mathrm{dV}}{\mathrm{V}} = \frac{\mathrm{T}\,\mathrm{C}_{\mathrm{V}}}{\mathrm{V}} \quad (\mathrm{T}\,;\mathrm{V}\,)\mathrm{dT}\,; \tag{2}$$

where $_{\rm T}$ is the isotherm al compressibility, (T;V) the G runeisen function, and C_V the heat capacity taken at constant volume. How ever, it is not easy to understand the low-tem perature saturation of a(T) below the tem – perature of the maximum in "⁰. The problem is related to the large number of observed anom alies in the vibration spectra of PM T (as well as in other relaxors) for tem peratures close to the dielectric maximum, like

increase in the generalized density of states at low $energies^{11,12}$,

anomalies in the behaviour of the longitudinal acoustic phonons^{15,43},

excess contribution to the speci c heat^{16,48}.

Hence, to estimate the in uence of each of this anomalies on the behaviour of a(T) using e.g. Eq. (2) is an extremely complicated problem. We note only that an invar-like behaviour generally can be described e.g by compensation of anham onic behaviour of di erent phonon modes⁴⁹ or striction. The electrostriction mechanism originally proposed in Ref.² can also give some contribution in the behaviour of a(T). Since a(T) is linear totem peratures well below T_d , it is unlikely that electrostriction is the only mechanism responsible for the temperature evolution of the lattice parameters in PMT.

V. CONCLUSION

To summarize, an extensive neutron study has been carried out in PMT and BMT com plex perovskites in the tem perature range 1.5 K { 730 K. The surface of di use scattering in a PMT single-crystal has been measured at T = 140 K.Crystal structure parameters have been re ned for both compounds. We found that lead ions are shifted from the 1a (0 0 0) W ycko position of the ideal perovskite structure and that the therm alm otion parameter of oxygen is an isotropic in PMT. The lattice param eter of BM T does not exhibit any anom alous behaviour. On the other hand, the lattice parameter of PMT shows two anom alies. One of them appears around T = 420 K which corresponds to the appearance of diffuse scattering and of the excess specic heat in PMT. The second anomaly is found close to the maximum of the dielectric susceptibility at T = 180 K . An obvious correlation in the behaviour of the lead displacem ents and of the neutron di use scattering intensity is observed in PMT. This indicates that lead displacements play a mapr rôle in the occurrence of di use scattering in PM T and probably also in other relaxor ferroelectrics.

A cknow ledgm ents

- ⁴¹ G. Burns et al. have measured the refraction index of PMN, PZN and Pb_{1 x} La_x $(Zr_{0:65}Ti_{0:35})_{1 x=4} O_3^{42}$, but to the best of our know ledge, the refraction index of PMT was never measured. Therefore, to determ ine the Burns tem perature T_d in PMT we rely on Brillouin light scattering data¹⁵. In the case of PMN the value of T_d extracted from Brillouin data⁴³ is in reasonable agreement with the original papers of G. Burns et al.⁴². We believe that this is the case also for PMT.
