A bstract. We compute the number of circuits and of loops with multiple crossings in random regular graphs. We discuss the importance of this issue for the validity of the cavity approach. On the one side we obtain analytic results for the in nite volum e limit in agreement with existing exact results. On the other side we implement a counting algorithm, enumerate circuits at nite N and draw som egeneral conclusions about the nite N behavior of the circuits.

1. Introduction

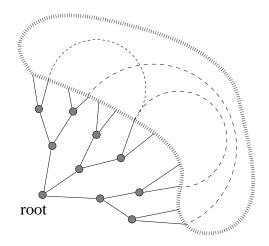

The study of random graphs, initiated more than four decades ago, has been since an issue of major interest in probability theory and in statistical mechanics. Examples of random graphs abound [1], from the original Erdos-Renyim odel [2], where edges are chosen independently of each other between pairs of a set of N vertices (with a xed probability of O (1=N)), to the scale-free graphs with power law degree distribution [3], only introduced in recent times. An interesting and useful distribution is the one that generates random c-regular graphs [4]. These are uniform by drawn from the set of all graphs over N vertices, each restricted to have degree c. R andom regular graphs can be easily generated when N is large (and c nite) [5], and an instance of 3-regular graph is symbolized in gure 1. A round a random by picked up vertex called root the graph looks like a regular tree. The probability that there exists a circuit (a self-avoiding closed path) of length L going through the root vanishes when N is sent to in nity and L is kept nitez [4].

The purpose of this article is to reach some quantitative understanding of the presence of long circuits in random graphs. Our motivation is at least two-fold.

First, in proving our know ledge on circuits in random graphs would certainly have positive fall-out on the understanding of equilibrium properties of models of interacting

z M ore precisely, this probability asymptotically departs from zero when $\log N = 0$ (L). Finite-length loops m ay be present in the graph, but not in extensive number.

Circuits in random graphs: from local trees to global loops

F igure 1. Structure of a random regular graph with degree c = 3. In the vicinity of a vertex (the root) the graph looks like a (regular) tree attached to the bulk. For any integer D, vertices at distance D from the root are almost surely distinct when the size N of the graph goes to in nity. No short loop, but m any long (dashed) ones pass through the root.

variables living on these graphs. For instance, frustration in spin systems emerge from the presence of circuits with odd length. The number of these circuits is therefore directly related to the amount of glassiness present in the system at low temperature. From the dynam ical point of view too, the properties of models of interacting or communicating agents e.g. routers, ... strongly depend on the topological properties of the underlying graph, and particularly upon feedbacks resulting from the presence of circuits. These \practical" incentives, together with purely academ ic motivations have led to recent studies on the distributions of unicyclic components [6] and cycles [7] in random graphs.

Secondly, the absence of short circuits in random graphs or, equivalently, the observation that random graphs essentially exhibit a local tree-like structure is crucial to the analytical treatment of spin models on random graphs with some common techniques, e.g. the replica or cavity methods. These models are characterized by (realistic) strong interactions between spins, in contrast to usual mean-eld systems, e.g. Curie-W eiss or Sherrington (K irkpatrick models. Yet, the absence of short-ranged bops in random graphs make them, around any vertex (root), locally similar to a tree surrounded by a remote bulk. Because of that one conjectures that the free-energy of a spin model on a random graph is equal to the one on the tree with self-consistent boundary conditions requiring that appropriate properties (for example the magnetization for the Ising model) are identical on the leaves and at the root vertex [8, 9, 10]. One of the goals of this note is to point out that this procedure a la Bethe amounts to make assumptions on the large-scale structure of random graphs, i.e. on the distribution of long bopsx.

x This point has certainly already come to m ind to researchers in the eld but it is, at the best of our know ledge, never explicitly mentioned in the literature.

We will rst discuss bops, and compute their number in the therm odynamic limit by analyzing the partition function of the Ising model. Next we will compute the number of circuits by discussing the n ! 0 limit of the 0 (n) ferrom agnetic model. For gathering information about the nite N behavior of the number of loops (or of the loop entropy) we will use an elective counting algorithm. We will end this note with a discussion of our notings and of the (many) open issues.

2. In nite size lim it: m ean-eld approach

In this section, we enumerate long loops in random graphs from the study of associated statisticalm echanics models. We will give our ad hoc de nition of a loop in the following section.

2.1. Loops with multiple crossings

Let us consider for example Ising spins $S_i = 1$ on vertices i = 1; :::; N of the graph of gure 1, and ferrom agnetic couplings $J_{ij} = 1$ on edges (i; j). To calculate the partition function Z () of the Ising model at inverse temperature on the graph of gure 1, we consider the leaves of the uncovered local tree i.e. vertices at distance D from the root (in gure 1 the maximum drawn distance is D = 2) [11, 8, 9, 12, 10, 13]. At su ciently large , a spontaneous, say, positive magnetization m is expected to be present in the bulk. As a result, the spins attached to the leaves will feel an external ed H > 0. Integrating these spins out will in turn produce an external eld H^0 acting on spins at distance D 1 from the root, with [1]

$$H^{0} = \frac{(c \ 1)}{t} \tanh^{1} [tanh() tanh(H)]:$$
(1)

A fler repeated iterations of this procedure, the eld at the root reaches a stationary value, H , from which we can derive the magnetization $m = \tanh[cH]$ and the free-energy density

$$f() = \frac{c}{2} \ln 2(e + e \cosh 2 H) + \frac{c}{2} \ln 2 \cosh \frac{cH}{c} : (2)$$

The critical inverse temperature is the smallest value of for which H is non zero i.e. $_{c} = \tanh^{1}\left(\frac{1}{c}\right)$.

As is well known, the high temperature expansion of the partition function Z of the Ising model can be written as a sum over closed paths going through each vertex an even number of times and each edge at most once [14]. Each path is given a weight (tanh)^L depending upon its length L. In the following we will refer to such paths as loops. G athering all loops with the same weight i.e. same length, we obtain

Z () =
$$2^{N} (\cosh)^{\frac{CN}{2}} M (L) (\tanh)^{L}$$
; (3)

Circuits in random graphs: from local trees to global loops

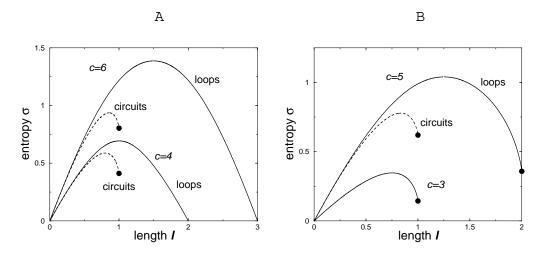

Figure 2. Entropy as a function of the length 'of loops (full curves) and circuits (dashed curves) for even (A) and odd (B) degrees c (for c = 3, loops and circuits coincide). The slope at origin is $\ln(c - 1)$ for both cases, the smallest loops being essentially circuits. B lack dots, with coordinates '₊; + identify the longest loops and circuits, see text.

where M (L) is the number of bops of length L that can be drawn on the graph. It is a sensible assumption that this multiplicity exhibits an exponential growth with the graph size,

$$M (L = 'N) = \exp[N (') + o(N)];$$
(4)

where 'is the intensive length of the loops, and is the entropy of loops having length '. We stress here that '= 0 (1) corresponds to L = 0 (N). Know ledge of the entropy will provide us with inform ation about large-scale loops i.e. with lengths of the order of N. Insertion of the above scaling hypothesis for M (L) in the partition function Z, and use of the Laplace method yield

$$f() = \ln 2 \frac{c}{2} \ln \cosh + \max [(') + \ln \tanh]$$
 (5)

in the in nite N limit. In other words, the free-energy density f() is essentially the Legendre transform of the loop entropy (').

We show in gure 2 our results for the loop entropy. The entropy departs from $\mathbf{\dot{h}} = \mathbf{0}$ with a slope equal to $\ln(\tanh_c) = \ln(c - 1)$ from $\mathbf{5}$ (. Its maximum is reached in $\mathbf{\dot{h}} = \frac{c}{4}$; $\mathbf{M} = (\frac{c}{2} - 1) \ln 2$, that is, for loops going through half of the edges. The left part of the entropy curve ($\mathbf{\dot{h}}$) is parametrized by inverse temperatures going from $_c$ ($\mathbf{\dot{e}} = 0$ (the para/ferro transition takes place when extensive loops start contributing to partition function Z) to 1 (top of the curve { at zero temperature, Z is dom inated by the most num erous paths). The right part of the entropy curve ($\mathbf{\dot{h}}$)

k Here we are assuming that not only the free energy density f is self-averaging (as is known and true) but that also enjoys the same property.

[{] Note that the nite slope at origin comes from the fact that the objects counted here (loops or circuits) are non local; one cannot gain entropy by rearranging edges independently [15].

5

is obtained when tanh > 1, that is, for inverse tem peratures with an imaginary part equal to $\frac{1}{2}$ allowing to transform the hyperbolic tangent of into the cotangent of its real part. This is done by considering a real > $_{c}$, the stationary eld H for this tem perature, and the transform ation $! + i_{\overline{2}}$, $(H) ! (H) + i(c 1)_{\overline{2}}$.

The case of even degree. For even c is left unchanged under the transform ation `! $\frac{c}{2}$ `. The right part of the entropy curve is thus the m intersymmetric of the left part with respect to `= `_M (gure 2A). This results from a duality between long and short extensive bops. Let ^F be the full bop (all edges occupied, which is allowed for even c). Then, for any bop with length `< $\frac{c}{4}$, ^F n (that is ^F without the edges belonging to) is a loop with length $\frac{c}{2}$ `. Notice that the largest loop is ^F, with length $\frac{c}{2}$.

The case of odd degree. Here duality does not hold and there is no simple transform ation rule for 'and . An explicit calculation gives the entropy curve shown in gure 2B. The maximal length ' $_{+} = \frac{(c \ 1)}{2}$ is reached with an in nite slope, and corresponds to a nite entropy $_{+} = \frac{1}{2}((c \ 1) \ln (c \ 1) (c \ 2) \ln c)$. For odd degrees c, indeed, loops cannot occupy all edges since the number of incoming edges onto each vertex is even. The longest loops have one free edge per vertex: these act as defects, the positions of which can be chosen with som e freedom, giving rise to a nite entropy. The larger is c, the smaller is the ratio $\frac{-t}{M}$: intuitively, the frustration coming from the parity of c is less and less in portant as c increases^t.

2.2. Loops without crossings: circuits

The iteration procedure can be applied to calculate the free-energy of other short-range m odels and then derive the entropies corresponding to large-scale diagram s generated through high tem perature expansions. For instance the ferrom agnetic O (n) m odel with n ! O gives inform ation on circuits i.e loops with vertices having degree 2 at m ost [16]. A spin S is submitted to two elds H₁; H₂ conjugated to the magnetization $\frac{S_1}{P_n}$ and its squared value. The iteration equations for these elds read

$$H_{1}^{0} = \frac{(c \ 1) \ H_{1}}{1 + H_{2}};$$

$$H_{2}^{0} = \frac{(c \ 1) \ (c \ 2)^{2} H_{1}^{2}}{2 \ (1 + H_{2})^{2}};$$
(6)

Inserting the xed point values for the elds in the expression of the free-energy per spin component,

$$f = \frac{1}{2} \ln (1 + H_2)^c + \frac{c(c - 1)^2 H_1^2}{2(1 + H_2)^2} + \frac{c}{2} \ln [(1 + H_2)^2 + H_1^2]; (7)$$

⁺ Num erical investigations of the one-step replica symmetry broken Ansatz for the Ising model with > 1 indicate that the replica symmetric solution is correct in this range of (complex-valued) temperature [15].

Higher moments are not relevant in the n ! 0 lim it.

Circuits in random graphs: from local trees to global loops

yields (for an alternative derivation, see [17]),

$$f = \frac{c}{2} \ln \frac{c(c-1)}{c-2} + \frac{c}{2} \ln [(c-1)]; \qquad (8)$$

The entropy of circuits,

$$(') = (1 \ ') \ln (1 \ ') + \frac{c}{2} \ ' \ln 1 \ \frac{2'}{c} + \ln (c \ 1);$$
 (9)

is obtained through $f() = \max[(') + \ln]$. Results are shown in gure 2. The maximal entropy, $M = \frac{1}{2}(c\ln(c-1) - (c-2)\ln(c+1))$, is reached $in_M = \frac{c}{(c+1)}$. The rightmost point, with coordinates $'_+ = 1$; $_+ = \ln(c-1) + \frac{1}{2}(c-2)\ln(1-2=c)$ corresponds to H am iltonian cycles. Expression (9) coincides with the output of rigorous calculations [2, 18], which shows the exactness of the replica symmetric hypothesis for the 0 (n ! 0) m odel [17]. Note the similarity of the entropy curves for loops on odd c-regular graphs and circuits (gure 2). In the two cases the slopes at minimal and maximal lengths are respectively nite and in nite, see the discussion above.

Let C = 3 and M = (L) be in all the rest of this note the num ber of circuits of length L in a random, c-regular graph. For nite L, M = (L) is asymptotically Poisson-distributed when N = 1 [4],

Proba[M (L) = M] =
$$\frac{1}{M!} \frac{(c \ 1)^{L}}{2L} \exp \left(\frac{(c \ 1)^{L}}{2L} \right)$$
 (10)

The above identity holds indeed for circuit-length L $$\log N$$. The expected number of circuits of intensive length '= L=N \$ is therefore, for '< $\frac{\log N}{N}$,

$$hM (')i = \frac{(c \ 1)^{L}}{2L} = \exp fN (') \quad \log (N) + \sim (')g ; \qquad (11)$$

with $(') = ' \log(c 1)$ and $\sim (') = \log(2')$. Note that this value of (') coincides with expression (9) at the rst order in '.

3. F in ite size corrections to circuit num ber: num erical results

To study what happens at nite N we have implemented a fast algorithm for nding all circuits in a given graph [19]. It is important that we explicitly nd, not only count, all the circuits so that by our method we can in principle give all interesting characterizations.

In our enum eration we rst generate a random graph and then count the circuits. We average this outcome over a number of samples. We describe the algorithm for enum eration in next section.

To generate a xed connectivity random graph we start by assuming that each site has connections that connect it to c dierent sites: we allow no self-connections and no double edges. At the beginning, all connections are free. Two of the connections are extracted and matched together. We continue lling them up (we use a table that we resize at each step to keep the process e ective) till all connections are set or we are stuck because there are two left connections that both belong to the same site or that belong to two sites that are already connected. To be sure not to introduce any system atic bias in this case we just discard the full graph and restart the procedure from scratch.

3.1. An algorithm for circuit enum eration

For enumerating circuits we have implemented and used an algorithm introduced by Johnson [19]. The algorithm inds all elementary circuits of a graph. The computer time needed for this task is bounded by O((N + E)(M + 1)), where N is the number of vertices of the graph, E the number of edges and M the total number of circuits in the graph: indeed one proves that the time used between the output of two consecutive circuits is bound by O(N + E) (and that this is true also for time elapse before the output of the rst circuit and after the output of the last one). The memory needed by the algorithm is bounded by O(N + E).

Let us just sketch the crucial steps of the procedure. One rst orders the vertices in some lexicographic sequence, and labels them with integers ranging from 0 to N 1. The search is started from a root vertex r, in the subgraph induced by r and by vertices after r: one of the crucial perform ance issues is that all vertices that become e roots are the smallest vertex in at least one elementary circuit. The input to the procedure is the adjacency structure A (v) for each vertex v, that represents the graph: it contains u if and only if (v; u) 2 E, where E is the set of edges of the graph.

We block a vertex v when it is added to a path beginning in r.We build elementary paths starting from r. The vertices of the current trial paths are loaded on a stack. A procedure adds the vertex to the path, if appropriate, and appends the vertex to the stack: the vertex is deleted from the stack when returning from this procedure. The ingenious part of the algorithm is in keeping a vertex blocked as long as possible, to m inimize the execution time. This has to be done while keeping the procedure correct: the basic rule that has to be satisfied to guarantee that all circuits are found (only once) is that if it exists a path from the vertex v to r that does not intersect the path loaded on the stack, then v has to be free (i.e. it cannot be in a blocked state). O ne uses a list to keep the inform ation needed to satisfy this constraint while staying time e ective.

Some details about perform ances are as follows: on an IntelX eon 2:8 G H z processor our in plem entation takes of the order of 0:07 seconds for noting all circuits of a N = 30 graph (they are 0 (50000)), 2:4s for N = 40 (0 (1:5 10^6) circuits) and 80s for N = 50 (with 0 (4 10^7) circuits).

In order to test the results of our code we have also implemented a \quick and dirty" backtracking procedure to count Ham iltonian circuits. Since our procedure crucially depends on the quality of the random number generator we have also checked that di erent (high quality) random number generators lead to statistically compatible answers.

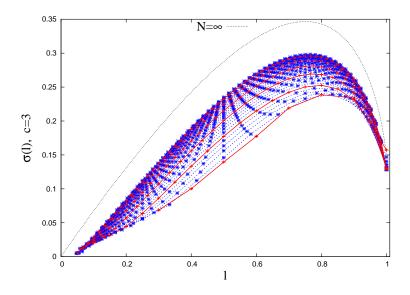

Figure 3. Circuit entropy $_{\rm N}$ (') as a function of ' for c = 3, and for graph sizes ranging from N = 10 to 64 (from bottom to top). The full curve corresponds to the analytical calculation of equation (9). Data for sizes multiple of 10 are made visible by using a di erent drawing style.

3.2. Results and interpretation

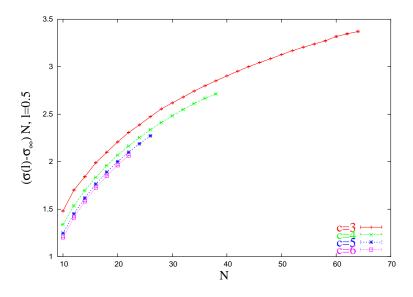

Thanks to our algorithm and implementation we have been able to enumerate of the order of 10^{14} circuits (a large number).

For small c values we can study larger graphs (we have analyzed graphs with up to 64 vertices in the c = 3 case and up to 22 vertices for c = 6, and averaged our results over samples ranging from 1000 to 10000 random graphs). Typically we nd for example of the order of 300 m illion circuits on a N = 56, c = 3 graph, one billion circuits on a N = 26, c = 5 graph and 1:5 billion circuits on a N = 22, c = 6 graph. For each value of N, we average over of the order of 10000 samples for all the c = 3 enum erations, and 1000 graphs for c > 3.

In gure 3 we plot the theoretical results obtained in the (replica symmetric) calculation of Section 2.2 for c = 3, together with results obtained by nite enumeration on nite lattices with N vertices. Numerical data from nite graphs are very slowly approaching the theoretical, in nite volume data. We try in the following to analyze the quality of this asymptotic agreement of the two sets of data.

At rst we know that loghM (')i ' log(c 1) as '! 0 where hM (')i is the average number of circuits of length $L = ' N \cdot W$ ith our num erical data we cannot work really close to '= 0, since for nite N we have a value 'm in that goes to zero as N ! 1 : nite size e ects appear as a attening of loghM (')i when ' becomes very close to the m inim um allowed value (see gure 3). One can easily see by eye that the slope is very sim ilar to the asymptotic slope in the small ' region where we are relatively safe from

nite size e ects. We have tted a linear behavior (that is indeed clear in the data) for example for ' in the range (:13;:19) for c = 3.

F igure 4.N times the difference between the circuit entropy and its asymptotic value, as a function of N for different connectivities c. Here '= 0.5.

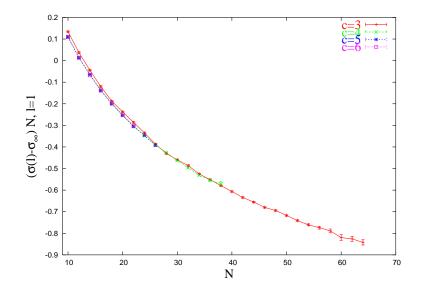

Figure 5. Same as in gure 4 but for H am iltonian circuits i.e. '= 1.

U sing this approach we nd for c from 3 to 6 slopes about 20% smaller than the theoretical prediction (on the larger graphs we can study): for c = 3 we nd 0.54 versus a theoretical log 2 0.69; for c = 4 we nd 0.87 versus 1.10; for c = 5 we nd 1.12 versus 1.39; for c = 6 we nd 1.31 versus 1.61. Finite size e ect can be drastically reduced if we com pare directly di erent c value (since we are using graphs of a size that is limited by the same criterion for each c value). For example the ratio of the slope of c and c + 1 is 0.62 for c = 3 versus a theoretical 0.63, 0.78 versus 0.79 for c = 4 and 0.85 versus 0.86 for c = 5. This really remarkable agreem ent gives us con dence that we have a good control over nite size e ects.

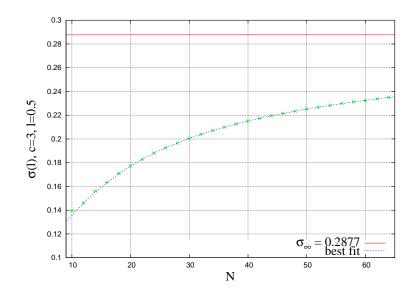

Figure 6. Circuit entropy (' = 0.5) versus N for c = 3 and best t to the form (13).

Equation (11) tells us that the di erence between the measured circuit entropy $_{\rm N}$ (') and the asymptotic value given by formula (9), once multiplied by N , behaves as

$$\binom{N}{N} \binom{N}{1} \binom{N}{1} = \log N + \sim \binom{N}{1}$$
 (12)

for vanishing small values of ', with ~ (') = $\log(2$ '). It is therefore independent of c, with a logarithm ic dependence upon the graph size N. To check how equation (12) applies to nite values of ', we look rst in gure 4 at the number of circuits with ' = 0:5, for di erent values of N and c (we have harvested our most precise data at c = 3). Data indeed show only a very weak dependence upon c, and this dependence becomes weaker with increasing c. Data for c = 5 are already indistinguishable from the ones for c = 6.

In gure 5, we show the same quantity for '=1 i.e. for H am iltonian circuits, that pass through all vertices of the random graph. As far as the scaling with c is concerned gure 5 shows that the scaling of H am iltonian circuits is excellent already at c = 3. W e will come back later about the fact that scaling property of H am iltonian circuits turn out to be very di erent from the ones of all other nite ', less dense circuits.

Inspired by the result obtained for sm all circuits (11), (12) we look for the following t for the circuit entropy for nite values of ',

$$_{N}$$
 (l) = $_{1}$ (l) + $c_{1}\frac{\log N}{N}$ + $c_{2}\frac{1}{N}$: (13)

In gure 6 we show our results for c = 3, = 0.5. The quality of the best t to data with sizes N 30 only is excellent, and is very good agreement with all data with N 12. The two parameter t is clearly superior to power law ts. We not that with very good accuracy (surely better than one percent)

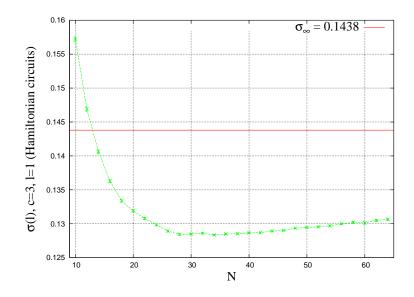

Figure 7. (l = 1) versus N for c = 3.

i.e. that even at nite 'the relation (12) gives the correct leading corrections. This result tells us that for all 'values (m aybe excluding '= 1, see later) we have that the average number of circuits of reduced length 'equals

hM ('N)
$$i = (K (') + o(1)) \frac{e^{N_{-1} (')}}{N};$$
 (14)

where K (') is a bounded function of '. For c_2 , we not values close to 1 e.g. :78 in the case of '= 0.5. Here precision is not as good since this is a sub-leading correction. W hat is clear from our data is that sub-leading corrections to the circuit entropy are of the order of 1=N as encoded in formula (14).

A swe have said above the case of H am iltonian circuits (= 1) is exceptional. Finite size transient e ects are very strong; this is intuitively expected since these circuits ll the graph and are deeply a ected by its nite size. We show in gure 7 the analogous of gure 6 but for = 1. It is clear that the structure of nite size e ects is completely di erent. On the contrary we have already explained that we not exactly the same behavior for all interm ediate 'values: the case '= 1 appears as isolated.

4. Conclusions

To sum up, the absence of sm all bops in random graphs allows one to argue that the free-energy of a spin m odel de ned on the graph is equal to the one on a regular tree with a self-consistent external eld at boundary (leaves). In turn, this free-energy fully determ ines the distribution of large-scale bops in the random graph. We stress that the whole complexity of this cavity procedure is actually hidden in the assumption of self-consistency for the eld(s) [20]. A ssumptions corresponding to broken symmetry in the replica framework [21, 22] m ay be necessary for m odels with random interactions.

A nyhow, the salient feature of the above standard approach is that it predicts global therm odynam ical quantities from local considerations about the graph only.

We have added to our exact computation, valid in the N ! 1 limit, results from exact enumeration at nite N. Thanks to them we have been able to determ ineprecisely the behavior of the leading corrections to the therm odynam ical behavior (at least for circuits with '< 1: we have found that H am iltonian circuits have stronger nite size corrections and a peculiar nite N behavior.

It would be very interesting to characterize properties or quantities that can adequately be described by a local procedure [23]. The question is how ever well beyond the scope of the present paper, which only shows that large loops are (rem arkably) among those ones.

A cknow ledgm ents

W e are grateful to G.Parisi for insights about the validity of replica symmetry for the Ising model with complex temperature. W e also thank S.Cocco, A.M ontanari for interesting discussions. R M. thanks the Les Houches summer school and the SMC-INFM Center in Rome for the hospitality in August and September 2003 respectively. E M. thanks the \Laboratoire de Physique Theorique" of ENS in Paris for a visiting professorship during May-June 2004.
