Abstract

In the context of spin electronics, the two spin-channel model assumes that the spin carriers are composed of two distinct populations: the conduction electrons of spin up, and the conduction electrons of spin down. In order to distinguish the paramagnetic and ferromagnetic contributions in spin injection, we describe the current injection with four channels: the two spin populations of the conduction bands (s or paramagnetic) and the two spin populations of the more correlated electrons (d or ferromagnetic). The redistribution of the conduction electrons at the interface is described by relaxation mechanisms between the channels. Providing that the d majority-spin band is frozen, s-d relaxation essentially concerns the minority-spin channels. Accordingly, even in the absence of spin-ip scattering (i.e. without standard spin-accumulation or giant magnetoresistance), the s-d relaxation leads to a d spin accumulation effect. The coupled diffusion equations for the two relaxation processes (s-d and spin-ip) are derived. The link with the ferromagnetic order parameter M is performed by assuming that only the d channel contributes to the Landau-Lifshitz-Gilbert equation. The effect of magnetization reversal induced by spin injection is explained by these relaxations under the assumption that the spins of the conduction electrons act as environmental degrees of freedom on the magnetization.

Spin-dependent transport in intermetallic ferromagnetic materials is usually described in the framework of the two spin-channel approximation. In this model the spin carriers are composed of two distinct populations: the conduction electrons of spin up (\uparrow), and the conduction electrons of spin down (\downarrow), which are defined by their conduction properties [1]. This model can be applied to ferromagnetic junctions and to hetero-junctions and it provides simple and operational descriptions of many effects related to spin dependent transport. The giant magnetoresistance (GMR) effect [2, 3, 4, 5, 6] is described by the diffusive spin-accumulation mechanism in normal / ferromagnetic junctions [6, 7, 8, 9, 10] and heterojunctions [11, 12] and also by interface scattering and/or band mismatch effects. Beyond the well-known GMR, which is due to the action of the magnetization on the spin of the conduction electrons, the opposite effect of the spin polarized current on the magnetization, the so called "current induced magnetization switching" or CIM S [13, 14, 15, 16, 17, 18, 19, 20, 21, 22] has also been treated in the framework of the two channel approximation (see the references [23] for the effects related to noncollinear magnetization).

Tremendous attention has been paid to the microscopic description of CIM S in terms of the dynamics of the spin of the conduction electrons in ferromagnets [24, 25, 26, 27, 28, 29, 30]. These approaches add a deterministic correction ("the spin torque") to the Landau-Lifshitz-Gilbert (LLG) equation due to the current, by identifying the spins of conduction electrons to the ferromagnetic order parameter. The old and uncomfortable discussion about paramagnetic vs. ferromagnetic character of itinerant spins (already problematic at equilibrium as discussed in the seventeen [31]) is implicitly evacuated. A careful study, however, of the different kinds of experiments performed about CIM S [32, 33, 34, 35, 36, 37, 38, 39, 40, 41, 42, 43, 44, 45] motivated in parallel the development of a stochastic approach, where the action of the spins of the conduction electrons on the magnetization is not direct, and is described in terms of environmental degrees of freedom. The magnetic order parameter and the spins of conduction electrons have not the same physical meaning. The most typical stochastic effect is the two level fluctuation and activation processes observed only under current injection over a time window range of a few nanoseconds [32, 35, 38, 43] to minutes [19]. Below the nanosecond time range, time resolved measurements (i.e. one-shot measurements) are not available but absorption peaks are measured in the electric power-spectrum at frequencies between 3 to 20 GHz [41, 42, 46]. These resonances can be thought of as a reminiscence of what is observed in ferromagnetic

resonance experiments, or noise measurements without spin-injection [47, 48] at these time scales only (sub-nanosecond), thermal spin-waves and precession of the magnetization are expected. This is the typical time scale of the dynamics of the magnetization. At the smaller coarse-grained level, electronic relaxations take place at time scales ranging from 10^{-12} to 10^{-16} second. These well separate time scales justify an approach in terms of Markovian processes in which the relevant slow variable is the ferromagnetic order parameter, and the fluctuations come from the relaxation of electronic spin degree of freedom.

The aim of this paper is to propose a phenomenological description of a possible mechanism of electronic relaxation (presented in Section I) which accounts for the fundamental difference between paramagnetic and ferromagnetic spin currents. In contrast to the paramagnetic current associated to the standard spin accumulation process and GMR, which does not interact directly with the magnetization, the ferromagnetic, or d channel current (the denomination "d channel" is a reference to the equilibrium description of itinerant d electrons [49, 50]) contributes to the ferromagnetic order parameter. The relaxation from paramagnetic channels (s channels) to the ferromagnetic channels (d channels), described as a diffusion process at the interfaces, leads to spin-transfer from injected current to the d current, through a new d spin accumulation process (Sections I and II). It is furthermore assumed that even this d contribution to the dynamics of the magnetization is not direct, due to the difference in the typical time scales. The d current injection is accounted for in terms of magnetic fluctuations or noise (Section III) and the after effect is to excite a large spectrum of magnetic and non-magnetic modes in the ferromagnetic layer.

This approach accounts for both the measured stochastic processes of the magnetization with a cut-off frequency beyond one GHz, and the observation of magnetization reversal by spin injection measured in single uniform magnetic layers (i.e. in the absence of giant magnetoresistance) [32, 38, 39, 40]. The approach adopted here is based on general arguments from irreversible thermodynamics, following the general method of De Groot and Mazur [51] or Stuekelberg [52].

Following the pioneering ideas of Mott [53], we assume that two electronic populations, referred to as s and d are relevant in order to describe the conduction properties of the ferromagnetic 3d metals and alloys. This hypothesis was used in order to describe the anisotropic magnetoresistance in these compounds [54], and to account for the contribution to the ferromagnetism of itinerant d electrons in equilibrium [49, 50]. In our context, the

s population describes the conduction electrons injected at the interface of a ferromagnetic nanostructure, and the d population describes the more localized electrons and associated spins, mainly responsible for the ferromagnetism of ferromagnets. The simplest extension of the two-channel approximation to our context is to divide both the s and d populations into up (") and down (#) spin populations (l is the internal variable describing the spin degree of freedom as defined in Ref. [55]).

Providing that the d majority spin band (") is fully occupied, s-d relaxation of " spin is negligible, and spin-conserved s-d relaxation only concerns the minority spin channels #. If we assume further that s-d relaxation with spin-flip is negligible with respect to spin-conserved s-d relaxation, a new mechanism of spin injection could then be described as parallel to the usual " # spin-flip relaxation used to describe spin accumulation and GMR phenomena [5, 9, 10].

I. THERMOKINETIC EQUATIONS

The system is composed by the reservoirs of the injected s electrons and the ferromagnetic layer composed by the d electrons. At the interface, current injection leads to a redistribution of the different electronic populations that are governed by spin polarization and charge conservation laws. Let us assume that the current injected is spin polarized in the down polarization (#). The conservation laws should be written by taking into account the reaction mechanisms between the different populations. At short time scales (electronic scattering) the relaxation channels are assumed to be the following four

- (I) $e_{s\#} \rightarrow e_{d\#}$ (spin-conserved s-d scattering)
- (II) $e_{s\#} \rightarrow e_{s"}$ (spin-flip scattering for the s population)
- (III) $e_{s\#} \rightarrow e_{d"}$ (spin-flip s-d scattering)
- (IV) $e_{d\#} \rightarrow e_{d"}$ (spin-flip scattering for the d population)

In a second step (at larger time scales), opposite relaxation mechanisms take place (involving ferromagnetic excitations) that are described in Sec. III. Process (I) is assumed to

be the main mechanism responsible for irreversible spin transfer. Process (II) leads to the well-known spin-accumulation effect and was described in detail with the same formalism elsewhere [15]. According to the fact that the majority-spin band is full and lies at a sizable energy below the Fermi level, the current $J_{d\uparrow}$ is negligible and the channel $d\uparrow$ is frozen. Processes (III) and (IV) are hence negligible [56]. Consequently, we are dealing with a three channel approximation.

The total current J_t is composed by the three currents for each channel $f_{s\uparrow; s\downarrow; d\downarrow}$: $J_t = J_{s\uparrow} + J_{s\downarrow} + J_{d\downarrow}$. In order to write the conservation laws, the relaxation rate $-\tau_{sd}$, is introduced to account for spin-conserved scattering, and the relaxation rate $-\tau_s$, is introduced in order to account for spin-flip scattering. Assuming that the current is flowing along the z axis, the conservation laws for a steady state regime are :

$$\begin{aligned} \frac{dJ_t}{dt} &= \frac{\partial J_t}{\partial z} = 0 \\ \frac{dJ_{s\uparrow}}{dt} &= \frac{\partial J_{s\uparrow}}{\partial z} - \tau_s = 0 \\ \frac{dJ_{s\downarrow}}{dt} &= \frac{\partial J_{s\downarrow}}{\partial z} - \tau_{sd} + \tau_s = 0 \\ \frac{dJ_{d\downarrow}}{dt} &= \frac{\partial J_{d\downarrow}}{\partial z} + \tau_{sd} = 0 \end{aligned} \quad (1)$$

The system is described by the number of electrons present in each channel at a given time, that defines the four currents, plus the entropy of the system. The conjugated (intensive) variables are the chemical potentials $f_{s\uparrow; s\downarrow; d\downarrow}$. As described in Appendix A, the application of the first and second laws of thermodynamics allows us to deduce the Onsager relations of the system :

$$\begin{aligned} J_{s\downarrow} &= \frac{s\downarrow}{e} \frac{\partial \mu_{s\downarrow}}{\partial z} \\ J_{s\uparrow} &= \frac{s\uparrow}{e} \frac{\partial \mu_{s\uparrow}}{\partial z} \\ J_{d\downarrow} &= \frac{d\downarrow}{e} \frac{\partial \mu_{d\downarrow}}{\partial z} \\ -\tau_{sd} &= L_{sd} (\mu_{s\downarrow} - \mu_{d\downarrow}) \\ -\tau_s &= L_s (\mu_{s\uparrow} - \mu_{s\downarrow}) \end{aligned} \quad (2)$$

where the conductivity of each channel $f_{s\uparrow; s\downarrow; d\downarrow}$ has been introduced. The first four equations are nothing but Ohm's law applied to each channel, and the two last equations introduce new Onsager transport coefficients (see Appendix A), L_{sd} and L_s , that respectively describe the spin-conserved relaxation (I) for minority spins under the action of the chemical potential difference $\mu_{s\downarrow} - \mu_{d\downarrow}$ and the spin-flip relaxation (II) under spin

pumping $J_s = J_s'' + J_{s\#}$.

The quantities of physical interest are the paramagnetic current $J_{0s} = J_s'' + J_{s\#}$, the minority-spin current $J_{0\#} = J_{s\#} + J_{d\#}$, and the two polarized currents $J_{\#} = J_{s\#} - J_{d\#}$ and $J_s = J_s'' - J_{s\#}$. We introduce the s and $\#$ conductivities $\sigma_s = \sigma_s'' + \sigma_{s\#}$ and $\sigma_{\#} = \sigma_{s\#} + \sigma_{d\#}$. The conductivity in balance $\sigma_{\#}$ and σ_s between respectively the $s\#$ and $d\#$ channels and the s'' and $s\#$ channels are:

$$\begin{aligned}\sigma_{\#} &= \frac{\sigma_{s\#} \sigma_{d\#}}{\sigma_{\#}} \\ \sigma_s &= \frac{\sigma_s'' \sigma_{s\#}}{\sigma_s}\end{aligned}\quad (3)$$

Eqs. (1) becomes :

$$\begin{aligned}\frac{\partial J_t}{\partial z} &= \frac{\partial J_{d\#}}{\partial z} + \frac{\partial J_s}{\partial z} = 0 \\ \frac{\partial J_{0\#}}{\partial z} &= -\sigma_s \\ \frac{\partial J_{\#}}{\partial z} &= 2\sigma_{sd} - \sigma_s \\ \frac{\partial J_{0s}}{\partial z} &= -\sigma_{sd} \\ \frac{\partial J_s}{\partial z} &= -\sigma_{sd} - 2\sigma_s\end{aligned}\quad (4)$$

and, defining the quasi-chemical potentials [57] $\mu_s = \mu_s'' + \mu_{s\#}$ and $\mu_{\#} = \mu_{s\#} + \mu_{d\#}$, Eqs. (2) becomes :

$$\begin{aligned}J_{0\#} &= \frac{\mu_{\#}}{2e} \frac{\partial \mu_{\#}}{\partial z} + \frac{\mu_{\#}}{\sigma_{\#}} \frac{\partial \sigma_{\#}}{\partial z} \\ J_{\#} &= \frac{\mu_{\#}}{2e} \frac{\partial \mu_{\#}}{\partial z} + \frac{\mu_{\#}}{\sigma_{\#}} \frac{\partial \sigma_{\#}}{\partial z} \\ J_{0s} &= \frac{\mu_s}{2e} \frac{\partial \mu_s}{\partial z} + \frac{\mu_s}{\sigma_s} \frac{\partial \sigma_s}{\partial z} \\ J_s &= \frac{\mu_s}{2e} \frac{\partial \mu_s}{\partial z} + \frac{\mu_s}{\sigma_s} \frac{\partial \sigma_s}{\partial z} \\ -\sigma_{sd} &= L_{sd} \mu_{\#} \\ -\sigma_s &= L_s \mu_s\end{aligned}\quad (5)$$

The equations of conservation [Eqs. (4)] and the above Onsager equations lead to the two coupled diffusion equations :

$$\begin{aligned}\frac{\partial^2 \mu_{\#}}{\partial z^2} &= \frac{1}{L_{sd}^2} \mu_{\#} - \frac{1}{\sigma_s^2} \sigma_s \\ \frac{\partial^2 \mu_s}{\partial z^2} &= \frac{1}{L_{sd}^2} \mu_{\#} - \frac{1}{L_s^2} \sigma_s\end{aligned}\quad (6)$$

where

$$\begin{aligned}
 l_{sd} &= \frac{r}{\frac{\#(1+\#^2)}{4eL_{sd}}} \\
 l_s &= \frac{r}{\frac{\#(1+\#)}{2eL_s}} \\
 l_{sf} &= \frac{q}{\frac{s(1+s^2)}{4eL_s}} \\
 l_{sd} &= \frac{q}{\frac{s(1+s)}{2eL_{sd}}}
 \end{aligned} \tag{7}$$

A solution of Eqs. (6) is

$$\begin{aligned}
 \# &= \frac{1}{2} + \frac{1}{2} \\
 s &= \frac{2}{s} \frac{1}{l_{sd}^2} \frac{1}{2} + \frac{1}{2} \frac{1}{l_{sd}^2} \frac{1}{2}
 \end{aligned} \tag{8}$$

with

$$\begin{aligned}
 1 &= a_1 e^{\frac{z}{+}} + a_2 e^{\frac{z}{+}} \\
 2 &= b_1 e^{\frac{z}{+}} + b_2 e^{\frac{z}{+}}
 \end{aligned} \tag{9}$$

where

$$2 = \frac{1}{2} (l_{sd}^2 + l_{sf}^2) \frac{1}{4} \frac{l_{sd}^2 l_{sf}^2 s^2 s_{sd}^2}{l_{sd}^2 + l_{sf}^2} A$$

The constants a_1, a_2, b_1, b_2 are defined by the boundary conditions. It can then be seen that the usual spin accumulation corresponding to s also depends on the spin-conserved s and electronic diffusion which is known to be efficient [56] and, conversely, that spin-conserved diffusion is able to lead to a spin accumulation, or a spin-accumulation effects. Accordingly, we expect to measure some typical effects related to spin-accumulation in single magnetic layers, or if $s = 0$: this point will be illustrated in the new expression of the magnetoresistance (Eq. (13) below), and in Section III through the effect of CIMS. s and relaxation adds a new contribution to the resistance, which plays the role of an interface resistance arising from the diffusive treatment of the band mismatch [2, 3, 4, 5, 6].

The resistance produced by the spin- \uparrow contribution (usually defined as the giant magnetoresistance R_{GMR}), plus the contribution of s and relaxation, are defined by

$$R_{GMR} = \frac{1}{J_t} \frac{Z}{1} \frac{1}{e} \frac{\partial}{\partial z} E_t^1 dz \tag{10}$$

where $E_t = \frac{\partial \phi_t}{e \partial z}$ is the total electric field and E_t^1 is the electric field far away from the interfaces. Providing that the total current is $J_t = J_{s''} + J_{s\#} + J_{d\#}$, or

$$J = -\frac{t}{e} \frac{\partial \phi}{\partial z} = -\frac{d\#}{t} \frac{\partial \phi}{\partial z} + \frac{s\#}{t} \frac{\partial \phi}{\partial z} + \frac{s''}{t} \frac{\partial \phi}{\partial z} \quad (11)$$

The total electric field can also be written (from Eqs. (2)) as

$$E_t = \frac{\partial \phi_t}{e \partial z} = \frac{J_t}{t} = \frac{1}{e} \left(\frac{\partial d\#}{\partial z} + \frac{s}{t} \frac{\partial \phi}{\partial z} + \frac{s''}{t} \frac{\partial \phi}{\partial z} \right) \quad (12)$$

where $t = s'' + s\# + d\#$, and $E_t^1 = \lim_{z \rightarrow \pm \infty} \frac{1}{e} \frac{\partial \phi}{\partial z}$. The resistance is given by :

$$R_{\text{GM R}} = \frac{1}{e J_t} \int_{-1}^{Z+1} \left(\frac{s}{t} \frac{\partial \phi}{\partial z} + \frac{s''}{t} \frac{\partial \phi}{\partial z} \right) dz \quad (13)$$

This three-channel model brings to light the interplay between band mismatch effects and spin accumulation, in a diffusive approach. It is interesting to note that the local neutrality charge condition which is often used (see for instance Eq. (4) in [58]) was not included. On the contrary, we have imposed the conservation of the current at any point of the conductor. Indeed, electron transfer from a channel to another where the electron mobility is different, induces a local variation of the total current.

II. NORMAL - FERROMAGNETIC INTERFACE

The resolution of Eqs. (6) leads to a variety of possible behaviours, from single interface effects to superlattice effects (see the paper by Valet-Fert [5] for the discussion in the framework of the two-channel approximation). Our main goal however is to understand the contributions of standard spin-accumulation and d spin-accumulation in uniform magnetic layers where no GM R are present due to the symmetry between both interfaces. We first focus our attention on a single interface separating two semi-infinite layers. If the ferromagnetic layer is at the right hand side, the solutions follow, from Eqs. (8)

$$\begin{aligned} \phi_1(z) &= b e^{-\frac{z}{L_+}} \\ \phi_2(z) &= d e^{-\frac{z}{L_-}} \end{aligned} \quad (14)$$

In our context, we define a "normal" metal as a compound with fully occupied d bands (the d'' and $d\#$ channels are frozen). In the normal metal (on the left hand side of the junction) we have $N_s = a e^{-z/L_{sf}}$.

At the junction, the continuity of the currents and the continuity of s , without interface resistance, becomes :

$$\begin{aligned} \frac{\partial d\#}{\partial z} \Big|_{0^+} &= 0 \\ J_{sl}^N(0) &= J_{sl}^F(0^+) \\ J_s^N(0) &= J_s^F(0^+) \end{aligned} \quad (15)$$

Where the superscripts N and F resp. stand for normal and ferromagnetic metals. The system originated from Eqs. (15) is solved in Appendix B. The three limiting cases of special interest are presented below.

Let us first consider the standard assumption where GMR and spin-accumulation are calculated. This case corresponds to both limits $l_{sd} \ll l_{sf}$ (i.e. instantaneous sd relaxation at the interface), or $l_{sf} \ll l_{sd}$ (no sd relaxation in the time scale of spin-ip relaxation). The simple case of two identical adjacent layers with opposed spin polarizations is generally considered [5]. In our context, this situation would correspond to a "quasi-ferromagnetic" metal in which both d and $d\#$ are frozen (i.e. there is no d ferromagnetism) but with $J_s^N = -J_s^F$, i.e. there is nevertheless a spin polarization of the current. The well-known solution is straightforwardly recovered. From the equations presented in Appendix B :

$$s = \frac{2e l_{sf}}{s(1 + \frac{s}{2})} J_t e^{-z/l_{sf}} \quad (16)$$

In the case of a junction with a "normal" metal $J_s^N = 0$ and a ferromagnetic metal $J_s^F \neq 0$, the well-known result is also recovered in both limits (with $J_s^N = J_s^F = J_t$ and $J_{sf}^N = J_{sf}^F$) :

$$s = \frac{2e l_{sf}}{s(1 + \frac{s}{2})} J_t e^{-z/l_{sf}} \quad (17)$$

In these two limits there is hence no modification due to the existence of the "d spin-accumulation" of the standard spin accumulation s . The d spin-accumulation however is not zero. In the case of a normal metal / ferromagnetic junction with $J^F = -J^N$, the d spin-accumulation is :

$$\# = \frac{e l_{sd}}{s(1 + \frac{s}{2})} J_t e^{-z/l_{sd}} \quad (18)$$

The corresponding contribution to the magnetoresistance is proportionnal to l_{sd}^2 and $\frac{1}{1 + \frac{s}{2}}$. This contribution is not zero even if the spin polarization of the current is vanishing ($J_s = 0$)

in the ferromagnet. Since l_{sd} is however expected to be very small, the spin-accumulation contribution should be important only for s close to $\frac{P}{2}$ (this is a consequence of the assumption $\mathbf{J}_{sf}^F = \mathbf{J}_{sf}^N$).

In intermediate cases, when l_{sf} is of the same order of magnitude as l_{sd} , the spin-accumulation s is non-vanishing even if s tends to zero.

III. GENERALIZED LANDAU-LIFSHITZ-GILBERT EQUATION

The question related to magnetization reversal under spin-injection is how the kinetics of the spins of the conduction electrons described in the previous sections is related to the ferromagnetic order parameter. In order to investigate this problem, we shall consider the different quantities that define our system (spins of conduction electron, electric charges, magnetization ...), and the corresponding relevant scales, or coarse-graining [59, 60, 61].

In our experimental context, the magnetization is a collective variable whose dynamics are much slower than all other paramagnetic spin relaxation mechanisms because the magnetization is conserved over the distance of the magnetic layer (or exchange length for spin waves), while the conservation of the electric charges is relevant over a local equilibrium of the order of the nanometer. It is then possible to identify three different time-scales. The first is the electronic relaxation (10^{-15} to 10^{-12} for paramagnetic transvers spin effects [26]), the second is the typical ("quasi-ballistic") dynamics of the magnetization (10^{-11} to 10^{-9}), and finally, the time scale of the activation processes measured over decades from 10 nanoseconds to hours. The electronic degrees of freedom, and especially the spins of the four electron populations defined in the first section can then be treated in terms of the action of an environment in a stochastic approach (e. g. defining a projection operator over the relevant variable \mathbf{M}_0 [59, 60, 61]). The effects of the spins of the conduction electrons are then reduced to the noise and the damping coefficient. Without current injection [15], the electronic degrees of freedom are contained in the Gilbert damping term [62, 63], and the following Gilbert equation for the magnetization \mathbf{M}_0 of the ferromagnetic layer is obtained [64]:

$$\frac{d\mathbf{M}_0}{dt} = \gamma \mathbf{M}_0 \times \left(\frac{\partial V}{\partial \mathbf{M}_0} + \frac{d\mathbf{M}_0}{dt} \right) \quad (19)$$

where γ is the gyromagnetic ratio and V is the magnetic Gibbs potential [65], where

H^{ext} being the external magnetic field. The coefficient is the Gilbert damping factor. Eq. (19) can also be put into the following Landau-Lifshitz form. In the case of uniform magnetization we have $\vec{M}_0 = M_s \vec{u}_0$, where M_s is the saturation magnetization and \vec{u}_0 the unit vector, so that it becomes:

$$\frac{d\vec{u}_0}{dt} = g^0 \vec{u}_0 \times \vec{\nabla} V - h^0 \vec{u}_0 \times \vec{\nabla} V \quad (20)$$

where $\vec{\nabla}$ is the gradient operator on the surface of a unit sphere. The phenomenological parameters h' and g' are linked to the gyromagnetic ratio and the Gilbert damping coefficient by the relations

$$\begin{aligned} h^0 &= \frac{\gamma}{(1+\alpha^2)M_s^2} \\ g^0 &= \frac{\gamma}{(1+\alpha^2)M_s} \\ \alpha &= \frac{h'}{g'} \end{aligned}$$

If we take into account the relaxation processes (I) to (IV), the conservation of the ferromagnetic spins normal/ferromagnetic interface is:

$$\frac{d\vec{u}}{dt} = g^0 \vec{u} \times \vec{\nabla} V - h^0 \vec{u} \times \vec{\nabla} V - \vec{f}_k(t) \vec{u} \quad (21)$$

where

$$\vec{f}_k(t) = \frac{g_{dB}}{g_B L} \int_{-L/2}^{L/2} J_{\#}^{\text{int}}(z) - J_{\#}^{\text{out}}(z) dz \quad (22)$$

L is the length of the magnetic layer, and g_{dB} is the magnetization per atom (number of Bohr magnetons) for the d population; g_B is the magnetization per atom of the ferromagnet, and the superscripts int and out describe respectively the interface for the incoming current, and the interface corresponding to the current flowing out of the layer. The $J_{\#}$ current is defined in Eq.(5) :

$$J_{\#} = \frac{\hbar}{2e} \left(\frac{\partial \psi}{\partial z} + \frac{\partial \psi^*}{\partial z} \right) \quad (23)$$

with the solutions given in Section II and Appendix B. Note that \vec{u} is no longer a unit vector due to the last term in the right hand side of the equation Eq. 21. Instead, \vec{u} includes

the fluctuations of \mathbf{u}_0 . After projection over \mathbf{u} , Eq. (21) gives the variation of the modulus of the magnetization due to current injection ([66]):

$$\frac{dkuk^2(t)}{dt} = \frac{g_d}{gL} k u_0^2 \int_{-1}^{+1} J_{\#}^{\text{int}}(z) J_{\#}^{\text{out}}(z) dz \quad (24)$$

and

$$kuk^2(t) = k u_0^2 e^{\int_{-1}^{+1} J_{\#}^{\text{int}}(z) J_{\#}^{\text{out}}(z) dz \frac{g_d}{gL} t} \quad (25)$$

The integral in the exponential is rather similar to that present in the calculation of the GMR, except that the current is the ferromagnetic spin current. For symmetry reasons equal and opposite electronic relaxations are expected to occur at both interfaces of the ferromagnetic layer : the effect of spin-injection should be compensated : $\int_{-1}^{+1} J_{\#}^{\text{int}}(z) J_{\#}^{\text{out}}(z) dz = 0$. We may still conclude that, if $d \ll \lambda$ spins do not interact with the magnetization and if the two interfaces of the ferromagnet are totally symmetric, the spin-transfer would vanish.

This is indeed what happens in the case of s population and GMR, where the energy due to the spin- $\uparrow\downarrow$ is transferred into the lattice and dissipated into the heat bath. This is simply due to the thermalization associated to paramagnetism. To that respect, the idea of conservation of momentum which leads to spin-transfer theories is not valide for paramagnetic spins, because the momentum dissipates into the heat bath and is not transferred into the ferromagnetic order parameter. In Eq. (21), the transvers stochastic force responsible for the fluctuations $f_z(t)$ has been put to zero because of the averaging over the equilibrium distribution ($\langle f_z(t) \rangle_0 = 0$): the transvers stochastic force is suppose to be the same with or without current injection and $\langle f_z(0) f_z(t) \rangle_0 = c kT(t)$ where T is the temperature of the lattice and $c = M_s$ [64].

In contrast, the energy dissipated or gained by $s \rightarrow d$ scattering is tranfered in the form of a contribution to the ferromagnetic order parameter within a typical time scales of the dynamics of the magnetization, and is not dissipated into the heat bath. Thus, the $d \ll \lambda$ spins do interact with the magnetization within a short distance. The process described in Eq. (25) can only be observed locally, and in the sub-nanosecond time range. Beyond, the behaviour of the magnetic layer will reflect the large spectrum of relaxation channels of the magnetization, from spin-waves, solitons, precession, soft modes etc. The detailed

description of these contributions is beyond the scope of the present paper, but the resulting behaviour of the magnetization can be described phenomenologically in terms of random fluctuations of the magnetization and effective temperature. Instead of Eq. (25), we have $\langle k^2 \rangle = \lim_{t \rightarrow \infty} \langle k^2(t) \rangle = 0$. At long enough time scales or thick enough layers, the last term in the right hand side of Eq. (21) is averaged out :

$$\langle f_k(t) \rangle = 0$$

The stationary transfer of spins, described here as environmental degrees of freedom, emerges in terms of transfer of energy (and entropy) through the non-vanishing fluctuations of the modulus of the magnetization. The fluctuation-dissipation relation, defines the current dependent effective temperature $T_{eff}(J_t)$ with the correlations:

$$\langle f(0)f(t) \rangle = e^{-kT_{eff}(J_t)t} \quad (26)$$

where k is the Boltzmann constant and e is an appropriate constant. The energy kT_{eff} is stored in the layer in form of magnetic fluctuations, and is not directly related to the temperature of the lattice. Accordingly, it is possible to transfer some few eV without damage in a nanoscopic sample (except if the fluctuations are generating spin-waves only, because spin-waves relax very rapidly into the lattice) [32]. It is also expected that the efficiency of the transfer is maximum if the layer thickness is large. This would explain the behaviour as the function of the temperature observed in ultrathin trilayer nanopillars [19, 36]; the amplitude of CIMS decreases while decreasing the temperature, and in long Ni nanowires [39] where the amplitude of CIMS is constant or increases while decreasing the temperature.

The effective temperature is proportional to $J_{\#}^2$, and depends, through α_s on the spin accumulation properties, and through $\alpha_{\#}$ to the d spin-accumulation. The fluctuations of the current $J_{\#}(t)$ are hence able to account for the effective temperature measured in some experiments of magnetization reversal [32, 34, 35, 38] in both single layer and trilayer systems. The effect described in terms of effective temperature is not directly sensitive to the sign of the current, but depends indirectly on the current direction through the sign of α_s and $\alpha_{\#}$, because it inverses the asymetry at the interfaces [5] in multilayered GMR devices. In contrast, the spin accumulation is symmetric in a single magnetic layer so that the

asymmetry of the interfaces is not necessarily modified by inverting the current. It is then possible to account for both the dependence to the current direction in trilayer structures [19, 20, 21, 22, 34, 35], and the absence of dependence in AMR single layer measurements [37, 39].

On the other hand, the resonance measured at the GHz frequency range [36, 41, 42] may be described by the magnetic excitations (precession and spin-waves, etc) produced during the relaxation of the modulus of the longitudinal magnetization \mathbf{u} into the ferromagnetic layer, while direct measurements of electronic resonances should be expected at the 10 to 100 GHz frequency range.

It is not possible to perform a direct estimation of spin transfer at the present stage of the description because the amplitude of the fluctuations strongly depends on specific magnetic properties of the sample and interfaces. A rough estimate can nevertheless be performed by observing that the typical current density injected at about $1.6 \cdot 10^7 \text{ A/cm}^2$, which corresponds to 10^{16} electrons per second injected at the interface. The current $J_{0\#}$ is a fraction of that (lets say above 1 % [49]). The question is to know what is the typical length l , or the time ($l = v \tau$) over which the magnetization is maintained out of equilibrium in the $d\#$ channel. The minimum relaxation time should be about 10^{-12} seconds, the maximum should be the typical magnetization dynamics, around 10^{-9} seconds. This means that the system is perturbed by a magnetization variation of 10^2 to $10^5 \mu_B$. Note that $2 \cdot 10^4 \mu_B$ corresponds to an energy transferred by the current of more than one eV in a local ferromagnetic field of 1 Tesla (in agreement with experimental results [32]). It is then possible to account for a transfer of magnetic momentum, with an energy largely beyond the Curie energy in the local field, and which would produce the magnetization reversal or magnetic excitations.

IV . CONCLUSION

A new electronic relaxation mechanism has been proposed under spin-injection at a normal/ferromagnetic interface. The description of the relaxation is based on a three-channel model that leads to a redistribution of electrons between paramagnetic and ferromagnetic spin currents at the interfaces. As a consequence, a new spin accumulation process of the electrons occurs. The coupled diffusion equations are derived and solved. The contribution of the d spin accumulation to the standard spin accumulation in the GMR is calculated.

The d spin accumulation adds a new contribution to the resistance, which plays the role of the interface resistance arising from the dispersive treatment of the band mismatch.

In contrast to the paramagnetic current (here associated to the standard spin accumulation process) which does not interact directly with the magnetization, the ferromagnetic, or d-channel current contributes to the ferromagnetic order parameter. It is furthermore assumed that even this d contribution to the ferromagnetic order parameter is not direct, due to the difference in the typical time scales. The d current injection is accounted for in terms of magnetic fluctuations or noise the consequence of which is to excite a large spectrum of magnetic and non-magnetic excitations in the ferromagnetic layer. This stochastic approach allows an effective temperature (or equivalently an effective potential barrier) to be defined in agreement with the experimental observations. The fluctuations depends, through the interband current $J_{\#}$, to both the usual spin accumulation $s = s_{\#} - s''$ and the d spin accumulation $s_{\#} = s_{\#} - s_{d\#}$. This mechanism allows the effect of current induced magnetization switching, including current-induced activation, to be described not only in multilayered structures exhibiting GMR, but also in uniformly magnetized nanostructures measured with AMR.

VI. APPENDIX A

The aim of this Appendix is to derive the Onsager matrix (2) on the basis of the first and second laws of thermodynamics. In a typical one dimensional junction the layer is decomposed into parts, defining the sub-system k , which is in contact to the "reservoirs" $k-1$ and $k+1$. The sub-system k , is then an open system which exchanges heat and chemical species with its left and right vicinity layers. Furthermore, the populations ($N_{s''}^k$, $N_{s\#}^k$, $N_{d\#}^k$) and spin down ($N_{d\#}^k$) are not conserved due to transitions from one channel to the other.

In this picture, the states of the sub-system k are described by the variables

$$(S^k; N_{s''}^k; N_{s\#}^k; N_{d''}^k; N_{d\#}^k) \quad (27)$$

where S^k is the entropy. The internal variables s'' , d'' and sd must however be introduced in order to take into account the relaxation processes occurring respectively between the two s-spin channels, the two d-spin channels, and the s-d relaxation.

Let us define the heat and chemical power by P^k (the mechanical power is zero as long as the action of the magnetic field on the charge carriers is neglected). The first law of the thermodynamics applied to the layer k gives

$$\frac{dE^k}{dt} = P^{k-1 \rightarrow k} - P^{k \rightarrow k+1} \quad (28)$$

Introducing the canonical definitions $T^k = \frac{\partial E^k}{\partial S^k}$ and $\mu_s^k = \frac{\partial E^k}{\partial N_{s''}^k}$; $\mu_d^k = \frac{\partial E^k}{\partial N_{d''}^k}$ the energy variation is:

$$\frac{dE^k}{dt} = T^k \frac{dS^k}{dt} + \mu_{s''}^k \frac{dN_{s''}^k}{dt} + \mu_{s\#}^k \frac{dN_{s\#}^k}{dt} + \mu_{d''}^k \frac{dN_{d''}^k}{dt} + \mu_{d\#}^k \frac{dN_{d\#}^k}{dt} \quad (29)$$

For the sake of simplicity, we limit our analysis to the isothermal case, $T^k = T$. The entropy variation of the sub-layer is deduced from the two last equations, after introducing the conservation laws and after defining the polarized currents $I_{\#} = (I_{s\#} - I_{d\#})=2$, $I_{\#} = (I_{s\#} - I_{d\#})=2$, and the currents $I_{\#} = (I_{s\#} + I_{d\#})=2$, $I_s = (I_{s''} + I_{s\#})=2$,

$$\begin{aligned} T \frac{dS^k}{dt} &= P^{k-1 \rightarrow k} - P^{k \rightarrow k+1} - \frac{1}{2} \mu_s^k I_{\#}^{k-1 \rightarrow k} - \frac{1}{2} \mu_{\#}^{k \rightarrow k+1} + \mu_{sd}^k - 2\mu_s^k \\ &\quad - \frac{1}{2} \mu_s^k I_s^{k-1 \rightarrow k} - \frac{1}{2} \mu_{\#}^k I_{\#}^{k-1 \rightarrow k} - \frac{1}{2} \mu_{\#}^{k \rightarrow k+1} - 2\mu_{sd}^k - \mu_s^k \\ &\quad - \frac{1}{2} \mu_{\#}^k I_{\#}^{k-1 \rightarrow k} - \frac{1}{2} \mu_{\#}^{k \rightarrow k+1} + \mu_s^k \end{aligned} \quad (30)$$

where we have introduced the chemical potentials $\mu_s^k = \mu_{s''}^k + \mu_{s\#}^k$, $\mu_{\#}^k = \mu_{s\#}^k + \mu_{d\#}^k$, and the chemical affinities of the reactions, defined by $\mu_s^k = \frac{\partial E^k}{\partial N_{s''}^k}$, $\mu_{\#}^k = \frac{\partial E^k}{\partial N_{s\#}^k}$, $\mu_{sd}^k = \frac{\partial E^k}{\partial N_{sd}^k}$.

The entropy being an extensive variable, the total entropy variation of the system is obtained by summation over the layers 1 to w where the layer 1 is in contact to the left reservoir R^L and the layer w is in contact to the right reservoir R^R .

The total entropy variation is:

$$\begin{aligned}
T \frac{dS}{dt} = & \sum_{R=1}^R \dot{Q}_R + \sum_{R=r}^r \dot{Q}_R \\
& + \sum_{k=2}^K \frac{1}{2} \left(\dot{Q}_s^{k-1} - \dot{Q}_s^k \right) I_s^{k-1,k} + \sum_{k=2}^K \frac{1}{2} \left(\dot{Q}_s^{k-1} - \dot{Q}_s^k \right) I_{0s}^{k-1,k} \\
& + \sum_{k=2}^K \frac{1}{2} \left(\dot{Q}_\#^{k-1} - \dot{Q}_\#^k \right) I_\#^{k-1,k} + \\
& + \sum_{k=2}^K \frac{1}{2} \left(\dot{Q}_\#^{k-1} - \dot{Q}_\#^k \right) I_{0\#}^{k-1,k} + \sum_{k=1}^K \dot{Q}_s^k - \dot{Q}_s^k + \sum_{k=1}^K \dot{Q}_\#^k - \dot{Q}_\#^k
\end{aligned} \quad (31)$$

where the two first terms in the right hand side of the equality stand for the heat and chemical transfer from the reservoirs to the system.

The entropy variation takes the form

$$T \frac{dS}{dt} = \sum_i F_i \dot{X}^i + P^{\text{ext}}(t) \quad (32)$$

where F_i are generalized forces and \dot{X}^i are the conjugated generalized fluxes. The variation of entropy is composed by an external entropy variation $P^{\text{ext}}(t)=T$ and by an internal entropy variation $dS^{\text{int}}=dt$.

By applying the second law of thermodynamics $dS^{\text{int}}=dt=0$ we are introducing the kinetic coefficients L_{ij} such that $dS^{\text{int}}=dt = \sum_i F_i \dot{X}^i = \sum_{ij} L_{ij} \dot{X}^i \dot{X}^j$. By identification with the expression (31), the kinetic equations are obtained, after performing the continuous limit,

$$\begin{pmatrix} \dot{J}_{0s} \\ \dot{J}_{0\#} \\ \dot{J}_s^d \\ \dot{J}_\#^d \\ \dot{Q}_s \\ \dot{Q}_\# \end{pmatrix} = \begin{pmatrix} L_{ss} & L_{s\#} & 0 & 0 & 0 & 0 \\ L_{\#s} & L_{\#\#} & 0 & 0 & 0 & 0 \\ 0 & 0 & L_{ss}^d & L_{s\#}^d & 0 & 0 \\ 0 & 0 & L_{\#s}^d & L_{\#\#}^d & 0 & 0 \\ 0 & 0 & 0 & 0 & L_{\text{int}}^s & 0 \\ 0 & 0 & 0 & 0 & 0 & L_{\text{int}}^\# \end{pmatrix} \begin{pmatrix} \dot{Q}_s \\ \dot{Q}_\# \\ \dot{Q}_s^d \\ \dot{Q}_\#^d \\ \dot{Q}_s \\ \dot{Q}_\# \end{pmatrix} \quad (33)$$

The kinetic coefficients are state functions; $L_{ij} = L_{ij}(S^k; N_+^k; N_-^k)$ and the symmetrized matrix is positive: $\frac{1}{2} (F_i L_{ji} + L_{ij} F_j) \geq 0$. The coefficients L_{int} refer to the internal relaxation processes [51]. According to Onsager relations, the kinetic coefficients are symmetric

or antisymmetric $L_{ij} = -L_{ji}$. The coefficients are known from the two-channel model for the conductivity. The two last equations concern the internal ("density" variables ρ_s and ρ_{sd} defined by $\rho_k = \frac{R}{k} \int_0^k \rho(z) dz$). Due to the Curie principle, there is no coupling between spin polarized transport processes and the electronic transitions (the scalar process is not coupled to vectorial processes).

VII. APPENDIX B

This Appendix is devoted to the general resolution of the coupled diffusion equations Eqs. (6) in the case of a junction between two semi-infinite layers with the conditions of continuity written below :

$$\begin{aligned} \frac{\partial \rho_{sd}}{\partial z} \Big|_{0^+} &= 0 \\ J_{s\#}^N(0) &= J_{s\#}^F(0^+) \\ \rho_s^N(0) &= \rho_s^F(0^+) \end{aligned} \quad (34)$$

Inserting the solutions given by (8) in Eqs. (34) and using Eqs. (5) the system becomes :

$$\begin{aligned} b_+ + d_+ &= \frac{2e l_{sd}^2 J_t}{t(1 + \#)} \\ a l_s^N l_{sf}^N + \frac{s\#}{s} J_t &= \frac{b_+}{e} - \frac{d_+}{e} \\ b_s^2 - l_{sd}^2 - l_+^2 + d_s^2 - l_{sd}^2 - l_{-}^2 &= a \end{aligned} \quad (35)$$

The b coefficient is given by :

$$\begin{aligned} b_+ &= \frac{1}{e} \left(\frac{1}{l_{sf}^2} + \frac{1}{l_+^2} + \frac{1}{l_s^N (1 + (\frac{N}{s})^2)} + \frac{l_{sf}^N}{l_{sf}^2} \frac{1}{e} + \frac{1}{e} \right) = \\ J_t \frac{e}{l_s^N l_{sf}^2} \frac{(1 + \frac{s}{N})}{(1 + \frac{N}{s})} l_{sf}^N &+ \frac{2 l_s^N l_{sf}^2 l_{sd}^2}{t(1 + \#)} - \frac{1}{l_{sd}^2} - \frac{1}{l_+^2} - \frac{(1 + \frac{s}{N})}{(1 + (\frac{N}{s})^2)} \frac{l_{sf}^N}{l_s^N l_{sf}^2} \end{aligned} \quad (36)$$

the d coefficient :

$$d = J_t \frac{e}{l_s^N} \frac{2 l_s^N l_{sd}^2}{(1 + \#) t} - b_+ \quad (37)$$

and the a coefficient :

$$a = \frac{2eJ_{sf}^N}{N_s(1 + \frac{N_s}{N_s})} \left(1 - \frac{2(1 - \frac{s}{s}) \frac{s^2 l_{sd}^2}{(1 - \frac{N_s}{N_s})(1 + \frac{N_s}{N_s})^2} + 2b_{sf}^N \frac{s(1 - \frac{s}{s})}{N_s(1 + \frac{N_s}{N_s})} + \frac{1}{2} - \frac{1}{2} \right) \quad (38)$$

For $l_{sf} = l_{sd}$:

$$b = \frac{l_{sf}}{2} \frac{eJ_t}{s} \frac{(1 + \frac{s}{s})(\frac{s}{s} - \frac{N_s}{N_s})}{1 - \frac{\frac{2}{s} + (\frac{N_s}{N_s})^2}{2}} \quad (39)$$

For $l_{sf} = l_{sd}$

$$b = \frac{eJ}{s} l_{sd} (1 - \frac{N_s}{N_s}) \frac{1 + \frac{\frac{s}{s} + \frac{N_s}{N_s}}{2}}{1 - \frac{\frac{2}{s} + (\frac{N_s}{N_s})^2}{2}} \quad (40)$$

- [66] Eq. (24) can also be justified on the basis of the Curie principle : the off-diagonal coefficients in the Onsager matrix are not zero only for variables of identical tensorial nature. In classical fluids, the chemical affinities (the scalars in our case) are only coupled to the

trace of the strain tensor. The corresponding term for the magnetization is the modulus of the magnetization [15].
