(Dated: March 23, 2022)

We study charge ordered d-wave resonating valence bond states (dRVB) in the doped cuprates, and estimate the energies of these states in a generalized t - J model by using a renormalized mean field theory. The long range Coulomb potential tends to modulate the charge density in favor of the charge ordered RVB state. The possible relevance to the recently observed 4×4 checkerboard patterns in tunnelling conductance in high T_c cuprates is discussed.

PACS numbers: 74.25.Jb, 4.20.-z, 74.72.-h

A number of recent STM experiments have shown spatial modulations in tunnelling conductance in high T_c cuprates [1, 2, 3, 4, 5]. More recent low temperature STM experiments have reported bias independent modulations of period approximately 4 - 4.5a (a: lattice constant) in the tunnelling conductance over a wide range of energy on underdoped Bi2212 [6] and NaCCOC [7]. Several theoretical proposals have been put forward to interpret the observed checkerboard charge ordering [8, 9, 10, 11, 12]. Chen *et al.* [10] have proposed that the modulations are due to Cooper pair density wave. Fu et al [11] have examined the possibility of a soliton crystal in a generalized Hubbard model including a nearest neighbor Coulomb repulsion and an antiferromagnetic spin exchange coupling. Anderson [12] has proposed an explicit wavefunction describing a Wigner solid of holes embedded in a sea of *d*-RVB state, and pointed out that the long-range Coulomb interaction furnishes the energy gain and the stiffness of the hole wavefunction opposes the deformation. The detailed calculations, however, have not been carried out in Ref. [12].

In the present paper, we study the charge ordered dRVB in the doped cuprates. We use a Gutzwiller projected wavefunction with both BCS pairing and charge ordering to describe the charge ordered state in cuprates. Our approach is similar to the idea outlined by Anderson [12], who formulated the charge ordering in a dRVB by a site-dependent fugacity, which was introduced by Laughlin in the context of Gutzwiller projected state in study of the Gossamer superconductivity [13, 14]. Here we shall use the renormalized mean field theory (RMFT) developed early [15, 16] to formulate charge ordering by site-dependent renormalization factors and estimate the energies of these states in the t - J model. We show that the long range Coulomb potential tends to modulate the charge density in favor of the charge ordered RVB state and that the favorable patterns for the charge ordering depend on the doping concentration. Our calculations suggest that the observed checkerboard patterns may well be induced by the long range Coulomb repulsion.

We consider a generalized t - J model with an addi-

tional long-range electron Coulomb potential,

$$H = H_t + H_s + H_c$$

$$H_t = -t \sum_{\langle i,j \rangle \sigma} c^{\dagger}_{i\sigma} c_{j\sigma} + hc$$

$$H_s = J \sum_{\langle i,j \rangle} \mathbf{S}_i \cdot \mathbf{S}_j$$

$$H_c = \frac{1}{2\epsilon} \sum_{i \neq j} \frac{\hat{n}_i \hat{n}_j}{r_{ij}},$$

where $c_{i\sigma}$ is an annihilation operator of a spin σ electron at site *i*. The sums in the kinetic and spin-exchange Hamiltonian H_t and H_s run over all the nearest neighbor pairs. $n_i = \sum_{\sigma} n_{i\sigma}$, and $n_{i\sigma} = c_{i\sigma}^{\dagger} c_{i\sigma}$. The sum in H_c runs over all the sites of *i* and *j*. ϵ is the dielectric constant, and r_{ij} is the spatial distance between the two sites *i* and *j*. An positive charge background to balance the charge neutrality is implied. There is a local constraint on every site, $\sum_{\sigma} c_{i\sigma}^{\dagger} c_{i\sigma} \leq 1$. In this Hamiltonian, H_c favors a charge ordering, while H_t prefers a uniform charge distribution.

We use the RMFT to estimate the energies of the charge ordered RVB states. The RMFT was developed for the t-J model to study a charge homogeneous RVB state [15, 16]. In that theory, one considers a Gutzwiller projected BCS state for the possible superconducting (SC) ground state. Here we shall extend it to the charge inhomogeneous case. We consider a Gutzwiller projected state,

$$|\Psi\rangle = P_G |\Psi_0\rangle,\tag{1}$$

where $|\Psi_0\rangle$ is a charge ordered BCS state, and $P_G = \Pi_i(1 - n_{i\uparrow}n_{i\downarrow})$ is the Gutzwiller projection operator. We use Gutzwiller's approximation to relate the expectation values of the kinetic or spin exchange energies in the projected state $|\Psi\rangle$ (denoted by <>) to the corresponding expectation values in the unprojected state $|\Psi_0\rangle$ (denoted by $<>_0$) by two different renormalization factors g_t and g_s :

$$\langle c_{i\sigma}^{\dagger} c_{j\sigma} \rangle \approx g_t^{ij} \langle c_{i\sigma}^{\dagger} c_{j\sigma} \rangle_0 \langle \vec{S}_i \cdot \vec{S}_j \rangle \approx g_s^{ij} \langle \vec{S}_i \cdot \vec{S}_j \rangle_0.$$
 (2)

The renormalization factors are determined by the ratio of the probabilities of the physical process in the projected and in the unprojected states [15, 16, 17, 18]. Similar to the method used [15] for the homogeneous case, we find

$$g_t^{ij} = 2\sqrt{\frac{(1-n_i)(1-n_j)}{(2-n_i)(2-n_j)}},$$

$$g_s^{ij} = \frac{4}{(2-n_i)(2-n_j)}.$$
(3)

They depend on the electron densities at the sites i and j. In the homogeneous case, $n_i = n$, g's are independent of the sites, we recover the results in Ref. [15], $g_t^{(0)} = 2x/(1+x)$ and $g_s^{(0)} = 4/(1+x)^2$, with x = 1 - n the hole density. The variational calculation of the projected state $|\Psi_0\rangle$ in H is then mapped onto the unprojected state $|\Psi_0\rangle$ in a renormalized Hamiltonian H_{eff} , given by

$$H_{eff} = H'_t + H'_s + H_c$$

$$H'_t = -t \sum_{\langle i,j \rangle \sigma} g_t^{ij} c^{\dagger}_{i\sigma} c_{j\sigma} + h.c.$$

$$H'_s = J \sum_{\langle i,j \rangle} g_s^{ij} \mathbf{S}_i \cdot \mathbf{S}_j.$$
(4)

Note that the intersite Coulomb interaction is not renormalized in the theory (*i.e.* the renormalization factor is 1).

Similar to the procedure in Ref. [15], we introduce two mean fields: a particle-hole amplitude field $\xi_{ij} = \sum_{\sigma} \langle c_{i\sigma}^{\dagger} c_{j\sigma} \rangle_0$, and a particle-particle pairing field $\Delta_{ij} = \langle c_{i\uparrow} c_{j\downarrow} - c_{i\downarrow} c_{j\uparrow} \rangle_0$. The renormalized Hamiltonian can then be solved by a self-consistent mean field theory. The energy of H_{eff} in the unprojected state, hence the energy of the generalized t - J model in the projected state can be written in terms of the self-consistent mean fields,

$$E = -\sum_{\langle i,j \rangle} \left[2t g_t^{ij} \xi_{ij} + \frac{3J}{8} g_s^{ij} (\xi_{ij}^2 + \Delta_{ij}^2) \right] + \sum_{i \neq j} \frac{n_i n_j}{2\epsilon r_{ij}}.$$
 (5)

In the uniformly charged dRVB state, $\xi_{ij} = \xi$, and $\Delta_{ij} = \pm \Delta$. The energy per site is found to be $E^{(0)} = -4tg_t^{(0)}\xi - (3J/4)g_s^{(0)}(\xi^2 + \Delta^2)$, where we have dropped out the long range Coulomb energy of a uniform electron density for it cancels to the energy due to the oppositely charged background.

In the inhomogeneous case, the self-consistent equations, or the Bogoliubov de-Genes equations, are more complicated. In what follows we shall make an approximation to replace the mean fields ξ_{ij} and Δ_{ij} by their average mean values obtained in the uniform dRVB state, and consider the effect of charge ordering on the kinetic and spin-exchange energies due to the renormalization factors g_t^{ij} and g_s^{ij} , and on the Coulomb potential. This is a rather dramatic approximation similar to what proposed by Anderson [12], but it should capture a substantial part of the effect of the charge ordering. The accuracy of this approximation will be examined in a limiting

FIG. 1: The mean fields Δ and ξ versus the hole concentration x in the uniform dRVB state. t/J = 3.

case, which turns out to be quite good. Within this approximation, the energy per site of the charge ordered dRVB state relative to the uniform dRVB state is,

$$\Delta E = \Delta E_t + \Delta E_s + \Delta E_c$$

$$\Delta E_t = (\bar{g}_t - g_t^0) \langle H_t \rangle_0 / N_s$$

$$\Delta E_s = (\bar{g}_s - g_s^0 \langle H_s \rangle_0 / N_s$$

$$\Delta E_c = e^2 / (2\epsilon N_s) \sum_{ij} (n_i n_j - n^2) / r_{ij}.$$
(6)

In the above equations, $\bar{g}_{t,s} = \sum_{\langle ij \rangle} g_{t,s}^{ij}/2N_s$, $\langle H_{t,s} \rangle_0$ is the average kinetic (spin exchange) energy in the uniform dRVB state. In practice, we first solve the RMFT for the uniform dRVB state, from which we obtain ξ , Δ , and $\langle H_{t,s} \rangle_0$. In Fig.1, we plot the two mean fields as functions of hole doping x for J/t = 1/3. We then calculate $\bar{g}_{t,s}$ and ΔE_c for various types of charge ordering patterns to estimate the energy of the charge ordered RVB state, and to determine the optimal charge distribution. The calculation of the long range Coulomb energy is similar to the calculation of the Modelung constant, and it converges rapidly with the appropriate choice of the method in summation.

Motivated by the approximate 4×4 charge ordered states observed in STM experiments, we consider several types of parent patterns shown below with periodicity of 4a along both directions in the square lattice. Each symbol represents a lattice site, and the sites marked with the same symbol have the same electron density.

$\circ \star \diamond \star$	$\circ \star \diamond \star$	0 * * *	0 * * *				
* ○ * ◇	* 0 * 0	○ ★ ◇ ★	$\circ \star \diamond \star$				
$\diamond \star \circ \star$	$\diamond \star \circ \star$	0 * * *	0 * * *				
$\star \diamond \star \circ$	* 0 * 0	0 0 0 0	$\diamond \circ \circ \circ$				
I	I	Ш	IV				

We denote $n_{\diamond} = n + \delta_1$, $n_{\circ} = n + \delta_2$, and $n_{\star} = n + \delta_3$. Since the overall average electron density of the system is n, only two out of the three $\delta's$ are independent. By using Eq. (4), we have $\bar{g}_{t,s}^I = \frac{1}{2}g_{t,s}^{\diamond\star} + \frac{1}{2}g_{t,s}^{\diamond\star}, \bar{g}_{t,s}^{II} = \frac{1}{4}g_{t,s}^{\star\star} + \frac{3}{4}g_{t,s}^{\circ\star}, \bar{g}_{t,s}^{II} = \frac{1}{4}g_{t,s}^{\star\star} + \frac{1}{4}g_{t,s}^{\circ\circ} + \frac{3}{8}g_{t,s}^{\star\circ} + \frac{1}{8}g_{t,s}^{\star\circ}, \text{ and } \bar{g}_{t,s}^{IV} = \frac{1}{4}g_{t,s}^{\star\star} + \frac{1}{8}g_{t,s}^{\circ\circ} + \frac{3}{8}g_{t,s}^{\star\circ}, here the superscript in <math>\bar{g}$ indicates the type of the parent pattern, and the superscript in g refers to the two sites with the marked symbols. The

FIG. 2: Low energy charge ordering pattern A1 of $4a \times 4a$ symmetry at hole density x around 1/16. Shown are $9 \times$ 9 patches. Each square represents a lattice site and the light (dark) square represents low (high) electron density.

Coulomb energy can be shown to be quadratic in $\delta' s$, and they are given by, in unit of $e^2/\epsilon a$,

$$\Delta E_c^I = -4.039\delta_1^2 - 4.039\delta_2^2 - 4.847\delta_1\delta_2$$

$$\Delta E_c^{II} = -1.497\delta_1^2 - 7.959\delta_2^2 - 3.468\delta_1\delta_2$$

$$\Delta E_c^{III} = -0.567\delta_1^2 - 3.772\delta_2^2 - 2.511\delta_1\delta_2$$

$$\Delta E_c^{IV} = -1.248\delta_1^2 - 4.138\delta_2^2 - 1.428\delta_1\delta_2.$$
(7)

Using these expressions, we have optimized the energy by varying parameters δ_1 and δ_2 , and obtained charge ordered states with lower energies. These states are derivatives of the parent patterns under the consideration, but may have a higher symmetry than the parent state for those sites marked with different symbols may have the same electron density. Below we shall discuss our results in three different regions of the hole concentration. In all of our calculations, we use J/t = 1/3, t = 0.3eV, $a = 3.8 \text{\AA}$.

At the hole density around 1/16, the lower energy charge ordering pattern is A1 as shown in Fig.2. There are only two types of the distinct sites in terms of the electron density in this pattern. The numerical values of the energy gain and the charge distributions are given in Table I for x = 1/16 and x = 0.05. All other patterns at these dopings have energies either higher than or too close to the energy of the uniform dRVB state $(\Delta E > -0.01 eV)$, and are not listed here. At x = 1/16, and $\epsilon = 1$, the lowest energy state has a charge distribution slightly deviated from a commensurate state with the light site completely empty (n = 0) and the dark site fully occupied (n = 1). At a larger ϵ , the energy gain decreases rapidly and the energy of the pattern A1is just slightly lower than that of the homogenous case at $\epsilon = 1.5$. There is no stable charge ordering pattern at ϵ much larger than 1.5. x = 1/16 is an ideal hole density for the pattern A1, which was also discussed in [11] and suggested in the magnetic and optical measurements [19, 20]. At x = 0.05, the pattern A1 is stable only for smaller ϵ , but is no longer stable for $\epsilon = 1.5$. Note that the pattern A1 at x = 0.05 is an insulator for there is no any connected path for holes to move through the lattice.

At the hole density around 1/8, there are several charge ordering patterns as shown in Fig.3. Among them the favorable pattern is B1. Patterns B2 and B4 have three types of distinct sites in terms of the electron density, while B1 and B3 have two types of distinct sites. The energy gain and the charge distribution are given in Table II for x = 1/8 and x = 0.1. Here we only list those patterns with relatively lower energies. As we can see from table II, at x = 1/8 the energies of patterns B1 and

TABLE I: The energy and charge distribution of pattern A1 at hole density x = 0.0625 and x = 0.05. An ideal hole crystal state with $n_{\blacksquare} = 1$ at x = 0.0625 is also listed for comparison.

FIG. 3: Lower energy charge ordering patterns for hole density around x = 1/8. B1 is of a symmetry of $\sqrt{8}a \times \sqrt{8}a$, and B3 is a stripe.

B2 are slightly lower than that of the homogeneous case at $\epsilon = 2$. At x = 0.1, the energy gain due to the charge ordering at $\epsilon = 2$ is already very tiny.

It is interesting to note that around the low hole density x = 1/8, both the checkerboard pattern B2 and the stripe pattern[21] B3 are SC states for holes in these patterns can move through the lattice.

At high hole concentrations, several new charge ordering patterns with lower energies appear, which are shown in Fig.4. In Table III, we list the energies and charge densities of the lower energy patterns at x = 0.15. For $\epsilon = 1$, the five patterns (B1, C1, C2, C3, and C4) have very close energies. In the pattern C's, the electron densities at the dark and grey sites are quite close. The empty sites in patterns B1 and C's form a $\sqrt{8a} \times \sqrt{8a}$ Wigner hole crystal. Among the series C, pattern C1 is a conducting phase. We do not find any lower energy charge ordering pattern at $\epsilon > 2.5$. At x = 0.2, the most favroable patterns are C1, C4 and the stripe pattern B3.

In the energy estimation for the charge ordered RVB state, we have focused on the effect of the charge density dependent renormalization factors, but neglected the site-dependence of the mean fields ξ and Δ . This approximation turns out to be quite good in a limiting case where all the holes are completely localized at a single site. Consider pattern A1 at x = 1/16 and pattern B1 at x = 1/8 with the electron density n either zero or

FIG. 4: Several lower energy charge ordering patterns at x = 0.15, not included in Figs 3. Patterns C1 and C2 are related by the interchange of the dark and gray sites, so for patterns C3 and C4.

1. In this limit, the kinetic energy vanishes. The spin exchange energy of the state can be estimated by a direct counting of the missing bonds due to the vacancies in an otherwise half filled background, which is given by $E_s = 2(1-2x)\alpha$ per site, with $\alpha = -0.344J$ the spin exchange energy per bond at the half filling. For J = 0.1eV we have $E_s = -0.060eV$ at x = 1/16 and $E_s = -0.052eV$ at x = 1/8, which are very close to the results obtained in the present MFT: $E_s = 0.063eV$ at x = 1/16 and $E_s = -0.054eV$ at x = 1/8.

In summary we have studied the charge ordered RVB states in the doped cuprates within a generalized t - J model by using a renormalized mean field theory. While the kinetic energy favors a uniform charge distribution, the long range Coulomb repulsion tends to spatially modulate the charge density in favor of charge ordered RVB states. Since both the Coulomb potential and the leading order in kinetic energy are quadratic in the density vari-

ation, we expect and indeed have found that the charge density variation from the uniform state is always large in the charge ordered state. The stability of the charge ordered RVB state strongly depends on the dielectric constant ϵ . In cuprates, $\epsilon \approx 2.5-5$. Our calculation suggests that the observed charge ordered state in STM experiments in cuprates may well be interpreted due to the long range Coulomb interaction. Among the favorable charge ordered superconducting states, pattern B1 has a symmetry of $\sqrt{8} \times \sqrt{8}$, patterns B2 and C1 both have checkerboard structure, and pattern B3 is a stripe. Because of the intersite Coulomb repulsion, we do not find the bound hole paris in the charged ordered states.
