We review recent progress on the statiscal physics study of the problem of coloring random graphs with q colors. We discuss the existence of a threeshold at connectivity $c_q = 2q \log q$ log q 1 + o(1) separting two phases which are respectivily COL (orable) and UNCOL (orable) with q colors; We also argue that the so-called one-step replica symmetry breaking ansatz used to derive these results give exact threshold values, and draw a general phase diagram of the problem.

Since the rst observation in 1852 by Francis G uthrie that any planarm ap could be colored with only 4 colors, graph coloring has grown to become an important problem both in combinatorial mathematics¹⁾ and in statistical physics.²⁾ G iven a graph, or a lattice, and given a number q of colors, it consists in assigning a color to each vertex such that no edge has two equally colored end vertices. When de ned on random graphs,³⁾ the problem turns out to be NP-C om plete and to display an interesting phase transitions at the so-called q-COL/UNCOL connectivity cq: graphs of average connectivity c < cq do have proper q-colorings with high probability (approaching one for graph size N ! 1), whereas graphs of higher connectivity require m ore than q colors. Here we review the recent progress on the statistical physics approach to the characterization of the phase diagram of this problem .

A very rst approximation for physicists working in disordered systems is the socalled annealed computation (the rst moment method in computer science). Take two connected vertices: the probability that they share the same color for a random assignment is 1=q, hence they have dimensions with probability 1 1=q. A crude estimate of the probability that a random conguration colors a graph of average connectivity c is easily obtained: there are dN = 2 links and each of them has a probability 1 1=q to be satis ed, therefore the number of COL congurations is

N (c) /
$$q^N$$
 1 $\frac{1}{q}$ $^{CN=2}$ / e^N $^{(c)}$; where (c) = $\log q + \frac{c}{2} \log (1 \ 1=q)$: (0.1)

It is straightforward to deduce from the preceding form ula the existence of a critical connectivity c_q 2qlnq lnq. For $c > c_q$, (c) < 0 and the number of COL assignments is vanishing exponentially with the size of the graph while for $c < c_q$, (c) > 0 and therefore there is an exponentially huge number of COL assignments: the COL/UNCOL transition is easily seen already at the annealed level. Such considerations are far from being only hand-waving; in fact, sim ilar computations, using the rst and second moment methods, allow to rigorously show that⁴⁾ 2qlnq lnq 1+o(1) c_q 2qlnq 2 lnq+o(1). To go beyond these inequalities, we turn toward the use of more complex statistical physics tools.

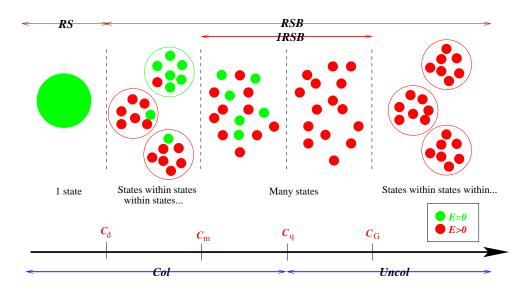

Fig.1. Generic phase diagram of the coloring problem on random graphs. The COL/UNCOL transition happens at c_q , but the phase diagram is more complex and the system also undergoes di erent replica symmetry breaking (see text).

It is quite in m ediate, for a statistical physicist, to realize that the coloring problem is equivalent to know ing if the energy of the ground-state of an anti-ferrom agnetic Potts m odel⁵⁾ on a random graph is zero (COL) or not (UNCOL). Inspired by spin glass theory,⁶⁾ one can use the replica/cavity approach to analytically study the problem, follow ing the sem inalwork of 7). In this particular context of constraint satisfaction problem s, the zero tem perature cavity m ethod is particularly well suited⁶⁾ and thanks to m any recent developm ents,^{8),9)} precise and detailed studies have been m ade possible.⁹⁾⁽¹²⁾ A lthough the m ethod is not fully rigorous, the self-consistency of the m ain underlying hypothesis has been checked in di erent optim ization problem s¹³⁾⁽¹⁵⁾ and therefore all the features of the solution derived by the statistical physics approach we will review here are conjectured to be exact results, not approximations. Of course, it is of rst importance to develop rigorous m athem atical approaches in order to con rm them.¹⁶⁾

The analytical results on the phase diagram are sum marized on Fig.1, it is very similar to the one nst observed for other optimization problems such as the K-Satis ability.¹³⁾ Let us discuss it for the particular case of the 3 coloring (we refer the readers to 11),12),15) for more details). When one varies the connectivity c, there actually exist many distinct phases, separated by thresholds connectivity cd, c_m , c_q and c_{SP} . The most important point is of course the critical COL/UNCOL transition that happens at $c_q = 4.69$. It separates the COL phases at $c < c_q$ from the UNCOL phase at $c > c_q$. But in the COL region, there actually exist distinct phases space. First, For $c < c_d$ ' 4:42, the set of COL assignments builds one cluster which is basically connected and from one single valley in the phase space. This phase is called the EASY-COL phase.

0 n the other hand, for $c > c_1$, this phase space becomes disconnected and the COL assignments are grouped into many clusters: this is the phenomenon of Replica Symmetry Breaking (RSB), familiar to anyone who had practiced mean eld spin glass theory. This phase space is characterized by the presence of many non-ergodic valleys and it is now impossible for any physical dynamics to get from one cluster to another. M oreover, the phase space develops m any m etastable states at higher energies (corresponding to UNCOL con gurations) and any too simple algorithm, such as steepest descent or simulated annealing, would get trapped into some these m etastable states in a same way aging system s undergo a glass transition; the COL region in this phase is thus said to be HARD-COL. For $c > c_{a}$, there are no more COL solutions and all valleys are UNCOL. In the whole RSB phase, the number of such valleys is growing exponentially with the size of the problem and the cavity method allows the computation of the logarithm of this number in a very similar way one computed the annealed logarithm number of COL solutions (c) in eq.(0.1). This quantity, which is called the complexity is a central element within the cavity m ethod. All these results where rst obtained by Zecchina and collaborators. $^{(1),(2)}$

This complex structure of the phase space is however very hard to study. In fact it is only when it is not too com plex, i.e. when con gurations simply group into valleys | the so-called one-step Replica Symmetry Breaking (1RSB) ansatz | that one is able to solve the equations. However the situation is generically much more com plex: we do have valleys within valleys within valleys etc ::: which obviously m ake the whole approach very di cult! In fact, m ost com putations are treating the phase space as if it was only 1RSB, neglecting the e ect of valleys within valleys. Recently, by studying m ore precisely the structure of this phase space, we show n^{15} that, luckily enough, there is a zone in this complex RSB phase which is indeed 1RSB; for the 3-coloring, it happens for q_m $4:51 < c < c_G$ 5:08. Even more luckily, it turns out that c_{α} , the COL/UNCOL threshold connectivity, is precisely inside this $\operatorname{zone}^{(15)}_{\ell}$ and that we are thus able to compute it without doing any approximation. In other word, the original computation $of^{(1)}$ was made in a stable 1RSB zone, and is therefore valid. This know ledge of the phase space allows us to draw a more complete and quite generic phase diagram (q.1) where we show all the di erent phases and transitions (COL/UNCOL, RSB/1RSB :::) that the system undergoes while varying connectivity.

It turns out that the feature of this phase diagram are the same for every number of colors q 3^{15} (as well as for other satisfaction problem $^{13),14}$). For instance, in the speci c case of random graph with xed connectivity (where graphs are still random but constructed in such a way that each vertexes have the same connectivity) one can derived analytically all critical connectivities for any number q of colors. We illustrate these computations in Fig2, where the di erent phases and transition discussed here are clearly seen. It can be checked directly that the critical COL/UNCOL transition always happens inside the 1R SB stable zone. Within this approach, we also show n^{15} that the value of the COL/UNCOL threshold is asym ptotically $c_q = 2q \log q \log q 1 + o(1)$, which agrees perfectly with mathematical bounds mentioned before.

To conclude, the statistical physics approach, via the cavity m ethod, of the coloring problem turns out to be rather fruitful. Not only it is consistent with indepen-

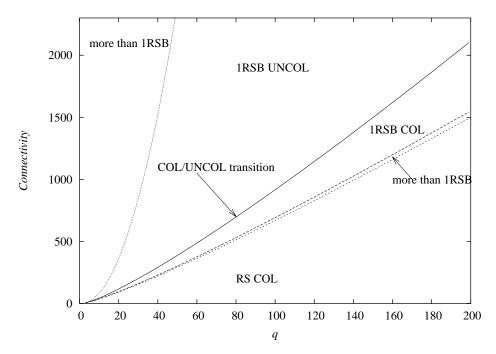

Fig. 2. Phase diagram of the q coloring problem on regular xed connectivity random graphs.

dently established rigorous m athem atical results, but it also allows for calculation and determ ination of the phase diagram and for a sharper, though not rigorous, determ ination of threshold values.

I would like to warm ly thank A .Pagnaniand M .W eigt for the collaboration that led to the a large part of the results presented here. I bene t from m any discussions with M .M ezard, F.R icci-tersinghi and R.Zecchina. I acknow ledge support from European Community's Hum an Potential program under contract HPRN-CT-2002-00319 (STIPCO), the ISIFoundation and the EXYSTENCE Network.
