(Dated: April 14, 2024)

W e consider a CNOT gate operation under the in uence of quantum bit- ip noise and dem onstrate that ac elds can change bit- ip noise into phase noise and thereby im prove coherence up to several orders of m agnitude while the gate operation time rem ains unchanged. W ithin a high-frequency approximation, both purity and delity of the gate operation are studied analytically. The num erical treatment with a Bloch-Red eld master equation con rms the analytical results.

PACS num bers: 03.67 Pp, 05.40.-a, 42.50 Hz, 03.65 Yz

D espite the remarkable experimental realization of qubits [1, 2, 3] and two-qubit gates [4] in condensed matter systems, the construction of a working quantum computer remains an elusive goal, not only due to de – ciencies of the control circuitry, but also due to the unavoidable coupling to the environment. Several proposals to overcome the ensuing decoherence have been put forward, such as the use of decoherence free subspaces [5, 6, 7, 8, 9], quantum Zeno subspaces [10], dynamical decoupling [11, 12, 13, 14], and coherent destruction of tunneling [15].

A single qubit under the in uence of bit-ip noise can be modeled by the spin-boson Hamiltonian  $H_0 =$  $\frac{1}{2}$  z + x; where x; denotes Paulim atrices and is a shorthand notation for the quantum noise specied below. The in uence of the bath is governed by the spectral density of the noise at the tunneling frequency =~. A possible driving eld may couple to any projection n of the (pseudo) spin operator ~, i.e., be pro-~. In Ref. [15], two particular choices portional to n have been studied and compared against each other: A driving of the form H (t) = A  $^{z} \cos(t) \operatorname{com} m \operatorname{utes} w$  ith the static qubit Ham iltonian while it modi es the bath coupling <sup>x</sup> in such a way that the spectral density of the bath at multiples of the driving frequency becomes relevant. For a proper driving am plitude, this elim inates noise with frequencies below the driving frequency which, thus, should lie above the cuto frequency of the bath. This scheme represents a continuous-wave version of dynam ical decoupling [15]. By contrast, a driving of the type H (t) = A  $^{x} \cos(t)$  renders the qubit-bath  $\cos$ pling unchanged but renorm alizes the tunnel splitting towards sm aller values and thereby causes the so-called coherent destruction of tunneling (CDT) [16, 17]. Then, decoherence is determ ined by the spectral density of the bath at a lowere ective tunnel frequency. For an ohm ic bath being linear in the frequency, the consequence is that both decoherence and the coherent oscillations in the rotating fram e are slowed down by the sam e factor [15]. Therefore, the number of coherent oscillations is not enlarged and, thus, for single-qubit operations, CDT might be of limited use.

In this work, we propose a coherence stabilization

scheme for a CNOT gate based on isotropic Heisenberg interaction [18, 19]. Our scheme does not su er from the drawbacks mentioned above because (i) it involves only intermediately large driving frequencies that can lie well below the bath cuto and (ii) it does not increase the operation time of the gate. Since we shall employ a eld that couples to the same coordinate as the quantum noise, the present coherence stabilization is di erent from dynamical decoupling.

CNOT gate with bit- ip noise. We consider a pair of qubits described by the Ham iltonian [18, 19, 20, 21]

$$H_{gate} = \frac{1}{2} \frac{X}{j_{j} + j_{j} + j_{j} + J \sim_{1} 2\gamma}$$
(1)

with a spin-spin coupling of the H eisenberg type, where j labels the qubits. In order to construct a quantum gate, the tunnel splittings  $_{j}$ , the biases  $_{j}$ , and the spin-spin coupling J have to be controllable in the sense that they can be turned o and that their signs can be changed. Then, a suitable sequence of interactions yields the CNOT operation [18, 19, 20, 21]

$$U_{CNOT}^{H}$$
  $U_{H}$  (=8)  $U_{1z}$  ()  $U_{H}$  (=8); (2)

where  $U_{1z}(') = \exp(i'_{1}^{z}=2)$  represents a rotation of qubit 1 around the z-axis and  $U_{\rm H}(') = \exp(i'_{1}^{z})$  describes the time evolution due to the qubit-qubit interaction. The symbol denotes equality up to local unitary transformations, i.e., transformations which act on only one qubit. Since we focus on decoherence during the stage of the qubit-qubit interaction, we take as a working hypothesis that one-qubit operations perform ideally. Thus, decoherence takes place while j = j = 0 and J > 0 during the required total qubit-qubit interaction time  $t_J = -24J$ .

The bit- ip noise is specied by the system bath H am iltonian  $H = H_{gate} + H_{coupl} + H_{bath}$  where  $H_{coupl} = \frac{1}{2} \int_{j=1,2}^{x} \int_{j}^{x} -c (a_{j}^{y} + a_{j})$  describes the coupling of qubit j to a bath of harm onic oscillators with frequencies ! and  $H_{bath} = \int_{j}^{x} -! a_{j}^{y} a_{j}$ . The bath is fully specied by its spectral density I(!) =  $c^{2}$  (! !). W ithin the present work, we consider the so-called ohm ic

spectral density I(!) = 2 ! exp( !=!\_c) with the dimensionless coupling strength and the cuto frequency !\_c. In order to complete the model, we specify the initial condition for the total density matrix to be of the Feynman-Vernon type, i.e., initially, the bath is in thermal equilibrium and uncorrelated with the system,  $tot(t_0) = (t_0)$  R<sub>bath,eq</sub>, where is the reduced density operator of the two qubits and R<sub>bath,eq</sub> / exp(  $H_{bath}=k_BT$ ) is the canonical ensem ble of the bath.

If  $k_B T$  is larger than the typical system energy J and the dissipation strength is su ciently small, 1, the dissipative system dynamics is well described within a Bom-Markov approach. There, one starts from the Liouville-von Neumann equation  $i_{tot} = [H; tot]$  for the total density operator and obtains by standard techniques the master equation [22]

$$= \frac{1}{ir} \mathbb{H}_{gate}; ] X \begin{bmatrix} X \\ j \\ j \end{bmatrix} X \begin{bmatrix} X \\ j \\ j \end{bmatrix} X \begin{bmatrix} X \\ j \\ j \end{bmatrix} X \begin{bmatrix} X \\ j \\ j \end{bmatrix}$$

$$\begin{bmatrix} X \\ j \end{bmatrix}$$

with the anti-commutator fA; Bg = AB + BA and

$$Q_{j}(t) = \frac{1}{4} \int_{0}^{Z_{1}} d d d! S(!) \cos(!) e_{j}^{x}(t) ;t):$$
(4)

Here, S (!) = I (!)  $\coth(~!=2k_B T)$  is the Fourier transformed of the symmetrically-ordered equilibrium bath correlation function  $\frac{1}{2}hf$  (); (0)gig of the collective coordinate = c ( $a^{y} + a$ ). The notation  $X^{e}$  ( $t;t^{0}$ ) is a shorthand for the H eisenberg operator U<sup>y</sup>( $t;t^{0}$ )X U ( $t;t^{0}$ ) with U being the propagator of the coherent system dynamics. Note that S (!) and I (!) are the same for both qubits due to the assumption of two identical environments. Replacing in Eq. (4) the term S (!)  $\cos(!)$  by I (!)  $\sin(!)$ , yields the operator P<sub>j</sub>(t). We emphasize that the particular form (3) of the master equation is valid also for an explicitly time-dependent H am iltonian.

The heat baths, whose in uence is described by the second and third term of the master equation (3), lead to decoherence, i.e., the evolution from a pure state to an incoherent mixture. Decoherence can be measured by the decay of the purity  $tr(^2)$  from the idealvalue 1. The gate purity (later referred to as \purity") P (t) =  $tr(^2(t))$ , which characterizes the gate independently of the speci c input, results from the ensem ble average over all pure initial states [23]. For weak dissipation, the purity is determined by its time derivative at initial time. Performing the ensem ble average, one nds the gate purity decay

P-(t) 
$$_{t=0} = 2 \operatorname{tr}() = \frac{2}{d(d+1)} \operatorname{Tr} ;$$
 (5)

where d = 4 is the dimension of the system Hilbert space and Tr denotes the trace in superoperator space de ned as  $Tr = \int_{a_{ja^{0}}}^{r} tr(\dot{a}^{0}) haj \dot{a} ha^{0}$  with figing being an arbitrary orthonom albasis of the system H ilbert space. It can be shown that the term containing P<sub>j</sub> does not contribute to Tr .

In order to evaluate for our setup the purity decay, we need explicit expressions for the operators  $Q_{i}$  and, thus, have to com pute the H eisenberg operators e (t ;t) for the H am iltonian H  $_0 = J \sim_1 2^{\circ}$ . This calculation is most conveniently done in the eigenbasis of H<sub>0</sub>, i.e. in the basis of the total (pseudo) spin  $\mathbf{L} = \frac{1}{2} (\sim_1 + \sim_2)$ . A fter perform ing the time and the frequency integration in Eq. (4), we nally arrive at  $P_{-}=\frac{2}{5}fS(0)+S(4J=~)g;$  where we have ignored Lamb shifts and de ned S (0)  $\lim_{1 \to 1^{-1}} S(!) =$  $4 k_B T = \sim$ . In particular, we nd that for low temperatures,  $k_B T$  . J, decoherence is dom inated by S (4J=~) such that P 16 J=5~. This value re ects the inuence of the so-called quantum noise which cannot be reduced by further cooling.

AC driving eb. In order to manipulate the coherence properties, we act upon qubit 1 by an ac eb which causes a time-dependent level splitting according to

$$H_{ac}(t) = f(t)_{1}^{x};$$
 (6)

where f(t) is a T-periodic function with zero timeaverage. Due to the nite driving time, which acts only while the Heisenberg coupling is switched on, the spectrum of the driving eld acquires a dispersion ! = k, where k is the number of driving periods. To keep the inuence of the dispersion small, we have to choose k 1.

N ext, we derive within a high-frequency approximation analytical expressions for both the coherent propagator U ( $t;t^0$ ) and the purity decay (5). We start out by transforming the total H am iltonian into a rotating fram e with respect to the driving by the unitary transformation

$$U_{ac}(t) = e^{i(t)} (t) (t) = \frac{1}{2} \int_{0}^{Z} (t) dt^{0} f(t^{0}); \quad (7)$$

which yields the likew ise T -periodic H am iltonian  $H^{\circ}(t) = U_{ac}^{\gamma}(t)H_{gate}U_{ac}(t)$ . For large driving frequencies J, it is possible to separate time scales and thereby replace  $H^{\circ}(t)$  by its time-average

$$H = (J \quad J_{?}) \stackrel{x \quad x}{_{1}} \stackrel{x}{_{2}} + J_{?} \sim_{1} 2^{*}$$
(8)

where the constant  $J_2 = Jhcos[2 (t)]i_T$  denotes an effective interaction \transverse" to the driving and h:::i\_T the time average over the driving period. W ithin this approximation, the propagator of the driven system reads

$$U_{e} (t;t^{0}) = e^{i (t) \frac{x}{1}} e^{iH (t t^{0}) = -e^{i (t^{0}) \frac{x}{1}}}$$
(9)

Having this propagator at hand, we are in the position to derive explicit expressions for the operators  $_{j}^{x}$  (t;t) and Q<sub>j</sub> and, consequently, also for the generator of the dissipative dynamics. The calculation is conveniently done in the basis of the total spin L and L<sub>x</sub> which, ow ing

to the relation  $\frac{x}{1} \frac{x}{2} = \frac{1}{2} \left( \frac{x}{1} + \frac{x}{2} \right)^2$  1, is an eigenbasis of the Hamiltonian (8). We insert the resulting expression for into Eq. (5) and nally obtain the purity decay

$$P_{-} = \frac{2}{5} fS(0) + S(4J_{2} = -)g:$$
(10)

0, we nd  $J_2 = J$  such that Eq. (10) agrees For f (t) with what we found in the static case; otherwise, the inequality  $jJ_2$  j < J holds and, thus, the bath correlation function S in Eq. (10) has to be evaluated at a lower frequency. For an ohm ic or a super-ohm ic bath, S (!) is a monotonously increasing function and, consequently, the ac eld reduces P- (unless  $J > !_{cuto}$ ).

The purity decay assumes its minimum for  $J_2 = 0$ . This condition marks the working points on which we shall focus in the following. For an ohm ic spectral density !, the purity decay at the working points be-I(!) = 2com es P=  $\frac{4}{5}$ S (0) = 8 k<sub>B</sub> T=5 for all tem peratures. This particular value has to be compared to the purity decay in the absence of driving: An analysis reveals that for  $k_B T > J$ , decoherence is essentially driving independent. By contrast for low temperatures,  $k_B T < J$ , the driving reduces the decoherence rate by a factor  $k_B T = 2J$ . The reason for this low -tem perature behavior is that for  $J_{?} = 0$ , the coupling operators  $\frac{x}{1}$  com mute with the effective H am iltonian (8) such that noise acts as pure phase noise with a strength proportional to the tem perature.

For a rectangular driving for which f (t) switches between the values A=2, the condition  $J_2 = 0$  yields  $A = \sim$  which corresponds to the application of two

-pulses per period. For a harmonic driving, f(t) =A cos(t)=2, one obtains  $J_2 = JJ_0$  (A=~), where  $J_0$  denotes the zeroth-order Bessel function of the st kind. Then, at the working points  $J_2 = 0$ , the ratio A = -assum es a zero of  $J_0$ , i.e., one of the values 2.405., 5.520., 8.654.., :::.

So far, we focussed on decoherence and ignored the inuence of the driving on the coherent dynamics. Since the driving changes also the coherent dynam ics, the pulse sequence of the CNOT operation needs a modi cation: At the working points of the driven system, the propagator (9) becomes  $U_{e}$  (t;t<sup>0</sup>) = exp[  $iJ_{1} \xrightarrow{x}{2}$ (t ť)=~1 and, thus, represents the time evolution caused by a socalled Ising interaction J  $_{1}^{x}$   $_{2}^{x}$ . This time evolution allows one to implement the alternative CNOT operation UCNOT exp(  $i_{1} x_{2}^{x}=4$ ) = U<sub>e</sub> (t+ t<sub>J</sub>;t) [21, 24]. Note that the interaction time  $t_J = -4J$  is the same as for the original gate operation  $U_{CNOT}^{H}$  . Since  $U_{ac}$  (2 = ) is the identity [cf. Eq. (7)], we assume for convenience that the driving period 2 = is an integer multiple of  $t_J$ , i.e. = 8kJ = w ith integer k .

Numerical solution. The calculation of the purity decay presented above relies on a high-frequency approximation which is correct only to lowest order in  $J{=}{\sim}$  . Thus, these should be compared to the exact num erical solution of the master equation (3). An ef-

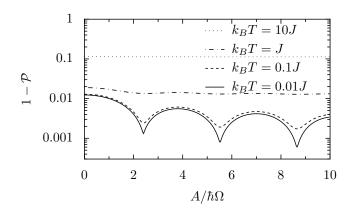

FIG.1: Purity loss 1 P during the Heisenberg interaction time  $t_{\mbox{\tiny J}}$  as a function of the driving amplitude for various tem peratures. The driving frequency is = 32J=~ and the = 0:01. For A = 0, the undriven dissipation strength 2 situation is reproduced.

cient scheme for that purpose is a modied Bloch-Red eld form alism whose cornerstone is a decomposition into the Floquet basis of the driven system [22]: According to the Floquet theorem, the Schrodinger equation of a periodically driven quantum system possesses a complete set of solutions of the form j (t) i =exp( i t=~)j (t)i, where the so-called F loquet states j (t) i obey the tim e-periodicity of the H am iltonian and denotes the so-called quasienergy. They are elements of an Hilbert space extended by a T-periodic time coordinate and are computed from the eigenvalue equation id=dt]j (t)i = j (t)i. In the Floquet ba-[H (t) sis fj (t) ig, the master equation (3) obtains the form <u>i</u> ( ; • • • • • The ben-) = 0 0 e tof this representation is that the time dependence of the original Ham iltonian has been elim inated by choosing a suitable basis. Moreover, for weak dissipation, we can replace within a rotating-wave approximation (t) by its time average [22]. Finally, we integrate the master equation to obtain the dissipative propagator which in tum allows to evaluate all quantities of interest.

In our num erical studies, we restrict ourselves to purely harm onic driving  $f(t) = A \cos(t) = 2$ . The resulting purity loss during the interaction time  $t_T$  is depicted in Fig. 1. We nd that for  $k_B T > J$ , decoherence is fairly independent of the driving. This behavior changes as the tem perature is lowered:  $0 \text{ nce } k_B T < J$ , the purity loss is signi cantly reduced whenever the ratio A =~ is close to a zero of the Bessel function  $J_0$ . Both observations con m the preceding analytical estimates. The behavior at the rst working point A 2:4~ is depicted in Fig. 2(a). For relatively low driving frequencies, we nd the purity loss being proportional to J= . There are signi cant deviations from the analytical result for small because the low -frequency regime is not within the scope of our analytical treatment. W ith increasing

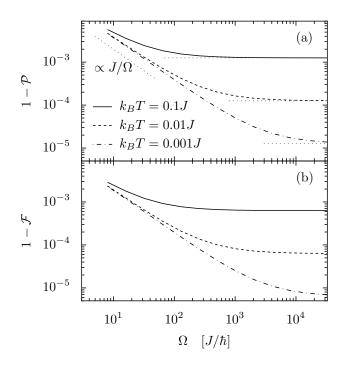

FIG. 2: (a) Purity loss during the Heisenberg interaction as a function of the driving frequency. The driving amplitude is adjusted such that 1 P assumes its rst minimum; i.e. A  $2:4 \sim , \text{cf. Fig. 1}$ . driving frequency, the discrepancy decreases until nally therm almoise dom inates decoherence. The num erical solution con m salm ost perfectly the results from the highfrequency approximation.

Still, there remains one caveat: The gate operation  $U_{CNOT}^{\perp}$  relies on the fact that  $U_{e}$  is a good approxim ation for the dynam ics of the driven gate because any deviation represents a coherent error. Therefore, we still have to demonstrate that such coherent errors are su ciently small. As a measure for this, we employ the so-called delity  $F = tr[_{ideal} (t_J)]$  [23] which constitutes the overlap between the real outcom e of the operation,  $(t_J)$ , and the desired nalstate  $_{ideal} = U_{I} (=4) _{in} U_{T}^{Y} (=4)$  in the average over all pure initial states. An ideal operation is characterized by F = 1. Here,  $U_{I}(') = \exp(i' \frac{x}{1} \frac{x}{2})$ denotes the propagator due to an ideal Ising spin-spin interaction. Figure 2(b) shows the delity defect 1 F of the real gate operation at the rst working point. In the relevant tem perature regime  $k_B T < J$ , we nd the crucial result that the delity defect is of the same order or even smaller than the purity loss. Thus, we can conclude that coherent errors are not of a hindrance.

In sum mary, we have put forward a strategy for reducing decoherence in a two-qubit quantum gate during the stage of qubit-qubit interaction. This coherence stabilization scheme is di erent from previous proposals in two respects: First, it does not rely on the manipulation of the coordinate that couples the qubits to the environm ent. By contrast, the central idea of our scheme is rather to suppress the coherent system dynam ics \transverse" to this sensitive system coordinate. In that way, the bit- ip noise, which produces unwanted transitions, is turned into pure phase noise which is proportional to the tem perature. This enables a coherence gain by cooling. The second di erence is that the proposed scheme elim inates also the noise coming from the spectral range above the driving frequency and, thus, is particularly suited for ohm ic noise spectra with large cuto frequencies. M oreover, the driven system still allows one to perform the desired CNOT operation with high delity and within the same operation time as in the absence of the control eld. Hence, the gained coherence time fully contributes to the num ber of feasible gate operations.

This work has been supported by the Freistaat Bayem via the quantum information initiative Q uanteninformation langs der A8" and by the Deutsche Forschungsgem einschaft through SFB 631.
