The gap function in unconventional superconductors may vanish at points or lines in momentum space, permitting electronic excitations, termed nodal quasiparticles, to exist at temperatures well below the superconducting transition. In the vortex phase, the presence of nodal quasiparticles should be directly observable through the variation of the heat capacity with the angle between a magnetic field and the location of the zeroes of the gap. The heat capacity of candidate non-magnetic unconventional superconductors $\text{Lu}(\text{Y})\text{Ni}_2\text{B}_2\text{C}$ were found to exhibit fourfold oscillations with field angle, the first such observation. The observed angular variations are in quantitative agreement with theory, confirming that quasiparticles are created via Doppler shifts at nodes along $\langle 100 \rangle$. Anomalous disorder effects have been also observed in the field-angle dependent heat capacity $C_p(T)$. In a slightly disordered sample, anomalous secondary minima along $\langle 110 \rangle$ appeared for $H > 1$ T, leading to an eightfold pattern. The coexistence of an anisotropic superconducting gap and nonlocal effects is shown to drive the anomalous behavior. These results demonstrate that field-angle-dependent heat capacity can be a powerful tool in probing the momentum-space gap structure in unconventional superconductors such as high T_c cuprates, heavy fermions, borocarbides, etc.

I. INTRODUCTION

Most superconductors behave conventionally; electronic excitations are suppressed by the BCS gap causing the electronic heat capacity, for example, to be exponentially small at temperatures well below the superconducting transition. Recently, a number of superconductors, cuprates¹ and heavy-fermion metals² among them, have been found to be unconventional in that they exhibit gap-zero (or nodal) points or lines in momentum space. Electronic excitations – nodal quasiparticles (nqp) – are then observed at low temperatures, giving rise to power-law rather than exponential behavior. Unlike gapless superconductivity, which can occur in conventional superconductors, the Fermi momenta of these quasiparticles are restricted to nodal regions of the Fermi surface, giving a strong directional dependence to various physical properties.

In 1992, Yip and Sauls proposed a nonlinear Meissner effect in the penetration depth of cuprate high- T_c superconductors.³ Since the effect uses the field-direction dependence of the supercurrent in locating the positions of the nodal lines (or points) of an unconventional gap in momentum space, it is a stronger test of the symmetry of the superconducting state than power-law behavior for the penetration depth. The search for the fundamental manifestation of d-wave symmetry has been very controversial from an experimental point of view.^{4,5,6,7,8} Li et al. questioned the observability of the nonlinear Meissner effect.⁹ They introduced nonlocal electrodynamics for a d-wave superconductor and found that the local nonlinear Meissner effect is not observable for fields below a crossover scale H^* describing the competition between nonlinear and nonlocal effects in the Meissner state. For

most orientations of the screening current, the crossover is of the same order as or greater than the lower critical field H_{c1} .

In conventional type II superconductors, the vortex cores play a crucial role in transport properties because a relatively high density of bound states is created there by the suppression of the local order parameter and extended quasiparticle states are completely gapped. In a new symmetry class such as cuprate superconductors, however, Hirschfeld et al. argued that extended quasiparticle states are dominant over vortex bound states because of the presence of the nodes.¹⁰ The anisotropy in the gap Δ_k in momentum space tied to the crystal axes will induce an angular anisotropy in the current response due to the coupling between quasiparticles and supercurrent, leading to the fourfold angular variation in field-angle thermal conductivity of unconventional superconductors with d-wave order parameter. In 1995, Yu and Salamon et al. demonstrated for the first time that the heat transport of YBCO oscillates with in-plane field angle.^{11,12} Subsequent experiments have confirmed the feature and thermal conductivity has been established as a tool that can probe the momentum-specific gap nature in unconventional superconductors.^{13,14,15} Such measurements, however, are complicated by the competition between Andreev-scattering and Doppler-shift effects.

A much more direct, and far more difficult, experiment is to detect the low-energy density of states of the nodal quasiparticles through its modulation by an in-plane field. Heat capacity provides such a measure. Working in the 2D limit, Vekhter et al. have shown that the density of states of a d-wave superconductor exhibits four-fold oscillation with field angle with respect to crystal axes.¹⁶ From the experimental standpoint, the search

for the oscillation has been puzzling.^{17,18} The expected 30 % of oscillation amplitude is within the reach of experimental error, but the effect has proven elusive. Whelan and Carbotte argued that the Zeeman energy splitting competes against the anisotropy.¹⁹ At a critical field H_c , Zeeman and Doppler energy scales become comparable and the DOS variation with field angle vanishes. Recently, Won and Maki used a semi-classical approximation and extended the 2D Vekhter model to a 3D superconductor with modulated cylindrical Fermi surface by including quasiparticles with an out-of-plane momentum component.²⁰ The 3D effect causes a strong suppression of the oscillation amplitude to around 6 %, making the observation much more difficult.

In this paper, we review the direct observation of a phenomenon that should be common to many so-called unconventional superconductors, those whose Cooper pairs have symmetries more complex than originally envisaged by Bardeen, Cooper and Schrieffer in their classic theory of superconductivity. If, in particular, the pairs have the symmetry similar to d-orbitals in atoms, there will be certain directions in momentum space in which electronic excitations, termed quasiparticles, can arise without an energy gap.

In section 2, the experimental method, sample preparation and characterization will be briefly explained. In section 3, the field-angle heat capacity of $\text{LuNi}_2\text{B}_2\text{C}$ is shown to be similar to results reported previously for $\text{YNi}_2\text{B}_2\text{C}$.³⁰ The magnetic field dependence will be analyzed by a Won-Maki extension of the Vekhter et al. calculation. The heat capacity dependence on magnetic

field angle will be discussed in terms of 3D nodal quasiparticle theory and used as a piece of confirming evidence that $\text{LuNi}_2\text{B}_2\text{C}$ and $\text{YNi}_2\text{B}_2\text{C}$ belong to a class of superconductors with nodes in gap function. An eightfold pattern appeared in a slightly disordered Lu1221 supports the coexistence of nonlocal effects and anisotropic gap effects. Then, concluding remarks will follow in section 4.

II. EXPERIMENTS

The electronic specific heat is a fundamental physical quantity that measures the electronic density of states (DOS) directly and is a bulk property. As noted in the Introduction, it was recently suggested that the specific heat can be used to study the angle-resolved gap structure of unconventional superconductors by studying the DOS variation with magnetic field angle.¹⁶ Considerable efforts have been expended to detect the field-angle variation arising from the anisotropic gap structure in unconventional superconductors, especially in YBCO.^{17,18} Those efforts, however, have suffered from intrinsic experimental limitations. First, a very limited set of field directions were investigated. Typically, the crystal axes and diagonal directions were chosen because they give the largest contrast in DOS for pure $d_{x^2-y^2}$ or d_{xy} pairing

FIG. 1: Sample assembly in ac calorimetry

symmetry. If the pairing symmetry is the mixture of two order parameters, such as $d+s$ wave, then the two directions do not represent gap-maximum or gap-zero (nodes) directions because the nodes move away from the diagonal directions. Second, temperature-variable heat capacity intrinsically contains large background contributions such as lattice vibrations or thermally excited quasiparticles. The large backgrounds cause an uncertainty in extracting the field-induced part, and can easily obscure the small angular variation.

With those problems in mind, we built a new specific heat probe designed exclusively to study the gap structure of superconductors in momentum space. Instead of varying temperature as was done in many previous works, we fixed temperature and magnetic field intensity and made the field angle as an only variable. This experimental scheme enabled us to study the small angular oscillation, which is typically less than 1 % of the measured heat capacity. Some of the key ingredients to this scheme are as following. First, temperature and magnetic field should be very stable. Otherwise, even a small fluctuation could obscure the small change with angle. A Physical Properties Measurement System (PPMS) by Quantum Design was used as a cryogenics platform to satisfy those conditions. Second, a stepping motor with a gear ratio 1:141 was used to rotate the sample and was controlled by a driver from PPMS. Instead of measuring limited directions, we were able to study the angle de-

FIG. 2: Upper panel shows the ϕ -angle heat capacity of optimally doped YBCO at 1.7 K and 7 T. The phase shift with ϕ -angle is shown in the lower panel. In both panels, the squares describe the data measured by the first pair of thermocouple wires and the circles by the second pair.

pendence of heat capacity in increments of 3 or smaller. Third, the heat capacity measurement should be sensitive enough to pick up the minute change with ϕ -angle. In addition, the measurement must be able to handle small single crystals because their weight is usually less than 1 mg. AC calorimetry was chosen because it has a sensitivity of up to 0.01 % of the measured heat capacity as well as a capability to measure even microgram (μ g) samples.²¹

The ac method used here is an adaptation of the Sullivan and Seidel technique.²² Fig. 1 shows the sample assembly. The front face of the sample was coated with colloidal graphite suspension (DAG) thinned with isopropyl alcohol to prevent a possible change of the optical absorptions of the sample. The sample was weakly coupled to the heat bath through helium gas and suspending thermocouple wires. At high temperatures, the thermal coupling can be adjusted mainly by controlling the amount of the helium gas surrounding the sample, while the thermal leak through thermocouple wires should be taken into account at cryogenic temperatures. As a heating source, infrared laser light ($\lambda = 789.2$ nm) was used. The light was modulated electronically to make a square-wave pulse and was guided into the PPM S sample space through

FIG. 3: The averaged ϕ -angle heat capacity of YBCO at 1.7 K and 7 T. The solid line shows a theoretical calculation of fourfold oscillation with the oscillation amplitude of 3.4 % (see text).

an optical fiber. The oscillating heat input incurred a steady temperature offset (or dc offset) against the heat bath with an oscillating temperature superposed. The measured oscillation temperature T_{ac} was converted to heat capacity by the relationship $C / T = T_{ac}$ in a proper frequency range.

In our ϕ -angle heat capacity measurements, two thermocouple pairs were used to measure the temperature oscillations T_{ac} simultaneously. The two sets of Au/Fe and chromel thermocouple wires were configured so that they were 90° apart, which enabled us to rule out the ϕ -angle contribution from the thermocouple wires due to ϕ -dependent thermopower of Au/Fe. If the angular oscillations come from our experimental setup, the two signals will be out of phase while they will be in phase with each other if they come from sample. As an example, we studied an optimally doped YBCO (Fig. 2). The squares in the top panel describe the angular heat capacity measured by the first pair of the thermocouple wires and the circles by the second pair. The two sets of data were measured simultaneously at 1.7 K and 7 T with magnetic field rotating within the CuO_2 plane of YBCO. Both of them show clear two-fold oscillations with ϕ -angle measured against a -axis. Note that the oscillations are out of phase with each other, indicating that they come from the thermocouple wires. The bottom panel of Fig. 2 shows the phase shift with ϕ -angle. There is no correlation with the heat capacity shown in the upper panel, confirming that the two-fold oscillation of the heat capacity is not related to intrinsic sample properties.²³

In Fig. 3, we show the averaged heat capacity of YBCO ($2C_{ave} = C_1 + C_2$). As expected, the two-fold components are almost suppressed. Now that the artifact from the experimental setup is removed, we can study the intrinsic sample property. The solid line describes a fit by a cusped fourfold variation with oscillation amplitude of

3.4 %, i.e., $C(\theta) = C_0 + C_4(1 + \cos 2\theta)$. Here, θ is the magnetic field angle with respect to the a -axis and C_4 is the oscillation amplitude. The periodicity is $\pi/2$ and the minima are located at $h110i$ directions, which are consistent with $d_{x^2-y^2}$ wave order parameter in YBCO where the nodes are located along $h110i$. The field-angle oscillation, however, is obscured by noise which is comparable to the angular change.

III. OBSERVATION OF NODAL QUASIPARTICLES AND NONLOCAL EFFECTS IN THE NONMAGNETIC SUPERCONDUCTORS $\text{Lu}(\text{Y})\text{NiB}_2\text{C}$

The discovery of RNiB_2C ($R = \text{Y}, \text{Lu}, \text{Tm}, \text{Er}, \text{Ho}, \text{and Dy}$) captured attention of the superconductivity community because of its relatively high transition temperature (T_c) and the coexistence of magnetism and superconductivity.^{24,25,26} The highest T_c 's in the borocarbide family are 16.5 K and 15.5 K in the nonmagnetic members with Lu and Y elements respectively. Amid the controversy over the pairing symmetry of the borocarbides, there is growing evidence that the gap function is highly anisotropic and possibly has nodes where the gap becomes zero in momentum space. In specific heat measurements, a power law behavior was observed in the temperature dependence and the electronic coefficient

(γ), to the extent it can be extracted, follows a square-root field dependence.^{27,28} Thermal conductivity measurements showed low energy excitations at as low as 70 mK and an anomalous magnetic field dependence similar to the unconventional superconductor UPt_3 but different from the exponential dependence characteristic of an isotropic s -wave gap.²⁹ Compelling evidence for the presence of nodes along $h110i$ directions has been reported from both z -axis field-angle thermal conductivity¹⁵ and field-angle heat capacity measurements of YNiB_2C .³⁰

Recently, a magnetic field-driven flux line lattice (FLL) transition has been observed both in the magnetic member (Er) and in the nonmagnetic members (Y and Lu) of the tetragonal borocarbides.^{31,32,33,34} The transition from square to hexagonal vortex lattice occurs due to the competition between sources of anisotropy and vortex-vortex interactions. The repulsive nature of the vortex interaction favors the hexagonal Abrikosov lattice, whose vortex spacing is larger than that of a square lattice. The competing anisotropy, which favors a square lattice, can be due to lattice effects (fourfold Fermi surface anisotropy)³⁵ or unconventional superconducting order parameter.³⁶ In this section, we present evidence that both the gap anisotropy and nonlocal effects coexist and the coexistence is the origin of the anomalous crossover from a fourfold pattern to an eightfold pattern in $C(\theta)$ with increasing field in LuNiB_2C .

FIG. 4: Temperature dependence of the in-plane resistivity of sample A (crosses) and sample N (circles).

A. Disorder effects

The best samples of LuNiB_2C exhibit behavior identical to that reported earlier for YNiB_2C ,³⁰ but disordered samples are significantly different. Three single crystals of LuNiB_2C from different batches were studied. Sample N was annealed at $T = 1000$ C for 100 h under high vacuum, while sample A and C were not annealed. The annealed crystal, sample N, showed the highest T_c (16.1 K) and residual resistivity ratio (RRR) of 27, while the unannealed sample A recorded the lowest T_c of 15.5 K and RRR of 16 (see Fig. 4), suggesting a judicious postgrowth annealing may improve the sample quality. The resistivity at T_c is 2.34 and 1.44 $\mu\Omega \text{ cm}$ for samples A and N, corresponding to mean-free paths of 144.5 and 234 Å respectively. Assuming that 16.1 K is the T_c for a pure sample, sample A is equivalent to 0.8 % of Co doping on the Ni site; i.e., $\text{Lu}(\text{Ni}_{1-x}\text{Co}_x)_2\text{B}_2\text{C}$ with $x = 0.008$.³⁷ Sample C with $T_c = 15.8$ K is less disordered than sample A.

For an isotropic s -wave superconductor, the contribution to the density of states (DOS) comes from the localized states in the vortex core. Since the density of vortices is proportional to the magnetic field, the field-induced DOS is linearly dependent on the field and $\gamma = 1$. For superconductors with line nodes, delocalized states leaking through the nodes dominate the DOS. When we integrate the contribution in a vortex unit cell and multiply by the density of vortices, the electronic DOS is proportional to \sqrt{H} in an intermediate region, i.e. $H_{c1} < H < H_{c2}$, where H_{c2} is upper critical field. This so called Volovik effect gives $\gamma = 0.5$ for line node and $\gamma = 1$ for point node.²⁸ Recently, there have been several reports that s -wave superconductors such as CeRu_2 ³⁹ and NbSe_2 ²⁷ behave like d -wave superconductors, show-

ing sub-linear magnetic field dependence in specific heat. Ichioka et al.⁴⁰ extended the Volovik calculation to the entire region, i.e. $H_{c1} < H < H_{c2}$. While the Volovik effect considered the delocalized states only, they included the localized states bound in a vortex core and the quasi-particle transfers between vortices. In their numerical calculation, the DOS dependence in the d-wave pairing states gives an exponent $\alpha = 0.41$, rather than Volovik's $\alpha = 0.5$. As for those with anisotropic s-wave pairing symmetry, the exponent becomes 0.67, which is clearly distinguishable from 0.5 or 0.41.

The disorder effects are also manifested in the magnetic field dependence of the electronic specific heat C_{el} . In pure samples (sample C and N), the low-temperature specific heat shows a H dependence in the mixed state, but there is a deviation from the H dependence at a finite field in the disordered sample A. Fig. 5 (a) shows the heat capacity of sample C at 2.5 K with increasing (circles) and decreasing (crosses) magnetic field along [100] direction. The dashed line which represents the least square fit of $C_0 + b(H - H_0)^{1/2}$ best describes the field dependence with $\alpha = 0.46$. Here C_0 is the zero-field heat capacity and the offset H_0 is essentially a lower critical field (H_{c1}) and 0.1 T was used for the least-square fit.

Figures 5 (b)–(d) show the heat capacity of the disordered sample A at 2.5, 4, and 8 K respectively. Low-field data were best described by the square-root field dependence (dashed lines) and the arrows indicate the points where the data deviate from the fit. The deviation field shows a systematic increase with temperature, i.e. 0.8 T at 2.5 K, 1.8 T at 4 K, and no clear deviation at 8 K. Above the deviation field, the data fall below the $H^{1/2}$ line.

B. Angle-resolved Specific Heat

In addition to the $H^{1/2}$ dependence in unconventional superconductors, the density of states $N(H; \theta)$ also depends on the orientation of the superfluid flow with respect to the nodes, which results in angular oscillation in $C(\theta)$.^{16,41} The supercurrent flow around a vortex leads to a Doppler energy shift, $E = v_s \hbar k$, where v_s is the velocity of the superfluid and $\hbar k$ is the Fermi momentum of nodal quasiparticles. When the field direction is normal to the plane containing nodes, the DOS is the average over the whole Fermi surface, leading to a square root field dependence. When the field is in the nodal plane, however, the Doppler shift has a field-direction dependence as well, $E = E_0 \sin \theta$.¹⁶ Here θ is an azimuthal angle of the gap node and ϕ is a vortex current winding angle. The energy scale associated with the Doppler effect is defined as

$$E_h = \frac{a \hbar v}{2} \frac{H}{H_0}^{1/2}; \quad (1)$$

where the geometrical constant a is order of unity, $v = \frac{\hbar v_F}{m \xi_0}$ is the average Fermi velocity, and ξ_0 is the flux

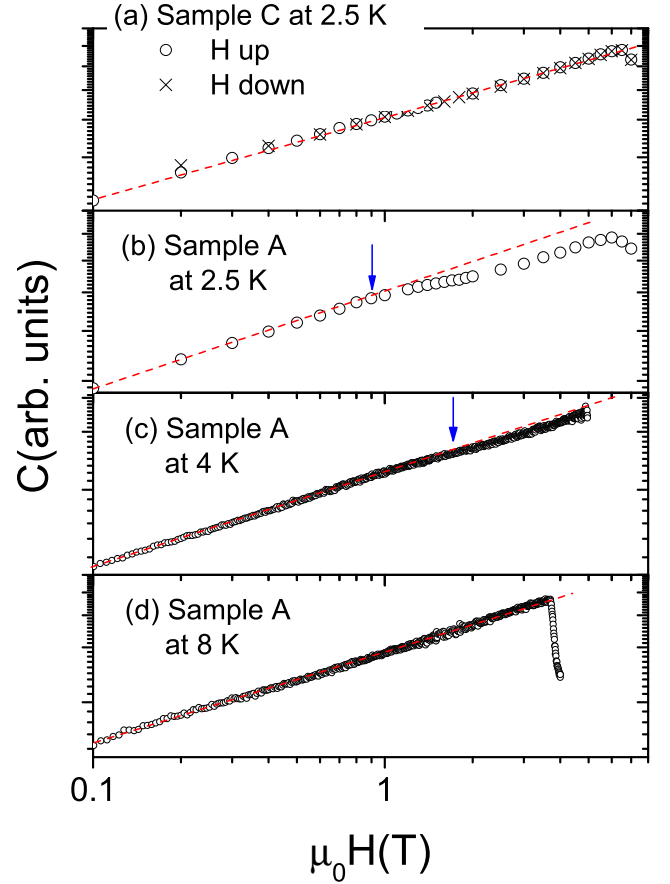

FIG. 5: (a) Heat capacity of sample C at 2.5 K for $H \parallel [110]$. (b)–(d) Heat capacity of sample A at 2.5, 4, and 8 K, respectively for $H \parallel [110]$. Dashed lines are $H^{1/2}$ fits and arrows indicate the deviation points from the $H^{1/2}$ dependence.³⁸

quantum. The variable $x = r/R$, where r is the distance from the vortex core and $2R$ is the intervortex distance. Working in the 2D limit, Vekhter et al. calculated the DOS, $N = (N_1 + N_2)/2$, for an in-plane magnetic field when $E_h \ll E_0$ where E_0 is the Matsubara frequency, and for four nodes at angles θ_n from orthogonal axes in a plane:

$$\frac{N_i(\theta; \hbar k)}{N_0} = \frac{\frac{1}{E_0} (1 + \frac{1}{2x^2})}{\frac{E_0}{E_1} [(1 + 2x^2) \arcsin x + 3x \sqrt{1-x^2}]} \quad (x = \frac{E_1}{E_0} = \frac{E_h}{E_0} \sin \theta_n) \quad (2)$$

where $i=1,2$, $E_1 = E_h |\sin(\theta_n - \phi)|$ and $E_2 = E_h |\cos(\theta_n - \phi)|$. The energy E_1 is for nodes close to the field direction, while E_2 is for nodes far from it. N_0 is the normal-state density of states.

When the magnetic field is along a nodal direction, $\theta = \theta_n + m\pi/2$ where m is an integer; the two nodal positions perpendicular to the field contribute fully, while the two parallel to the field do not contribute at all because the Doppler shift is an inner product between the superfluid velocity v_s and the quasiparticle momentum $\hbar k$. When the field is along a maximal gap direction ($\theta = \theta_n + (2m+1)\pi/4$), in contrast, all four nodal points

contribute equally to the DOS with a factor of $\frac{1}{2}$ less than the full contribution. When we add all the contributions, the total DOS has minima along nodal directions and maxima along gap directions. At $T = 0$ K, the oscillation is cusped with a contrast of $\frac{1}{2}$ between the minima and the maxima and is independent of the magnetic field. At a finite temperature, however, the sharp contrast is washed out due to thermal effects, leading to more rounded minima and the DOS oscillation now depends on the magnetic field.

The oscillation amplitude depends on the gap geometry and dimensionality of the superconductors. The Vekhter et al. model above assumes the Fermi momentum of nodal quasiparticles (nqp's) to be restricted to the nodal plane. A more realistic calculation, therefore, is to allow nqp Fermi momentum out of the nodal planes, which decreases the amplitude of the angular variation.²⁰ We account for the 3D effect by replacing the Doppler-related energies E_1 and E_2 by $E_1^{3D} = E_h [\sin^2(\theta_n) + \cos^2 \theta]^{1/2}$ and $E_2^{3D} = E_h [\cos^2(\theta_n) + \cos^2 \theta]^{1/2}$ respectively and integrate the DOS over polar angle θ :

$$N(\omega; h; \theta) = \frac{1}{2} \int_0^{2\pi} \frac{1}{2} [N_1(\omega; h; \theta; \phi) + N_2(\omega; h; \theta; \phi)] d\phi : \quad (3)$$

The qualitative features are the same as those in the 2D case except that the oscillation amplitude decreases from 41 % to 6 % in 3D superconductors at $T = 0$ K. The 3D effect was indeed confirmed experimentally in the field-angle heat capacity measurement of $\text{YNi}_2\text{B}_2\text{C}$.³⁰ We note that a similar effect is predicted for an (s+g)-wave superconductor.⁴²

The upper panel of Fig. 6 shows the field-directional angular dependence of the total heat capacity at 2 K and 0.6 T, where the transverse magnetic field was rotated within the basal plane of $\text{LuNi}_2\text{B}_2\text{C}$. The total heat capacity consists of constant, 2-fold, and 4-fold contributions: $C_{\text{total}}(\theta; H) = C_0 + C_2(\theta; H) + C_4(\theta; H)$. The field-independent constant C_0 is due to nonmagnetic contributions, such as the lattice heat capacity and thermally excited nqp's, and is determined experimentally from $C(T)$ at 0 T. The 2-fold contribution $C_2(\theta; H)$ comes from our experimental setup and has a functional form of $c_2 \cos 2\theta$. The Au/Fe and chromium thermocouple wire is a major source of this contribution, but misalignment of the basal plane of the sample against the field direction could also lead to the 2-fold component because of the anisotropy between in-plane and c-axis heat capacities. The dashed line in the upper panel of the Fig. 6 is $C_2(\theta; H)$; the 2-fold signal is about 40 % of the 4-fold component at 0.6 T and increases with magnetic field.

The lower panel of the Fig. 6 shows the 0.6 T data after subtraction of the 2-fold and the lattice components: $C_4(\theta; H) = C_{\text{total}}(\theta; H) - C_2(\theta; H) - C_0$. The 4-fold variation is clearly seen. To make a quantitative analysis, we fit our data to $C_4(\theta; H) = c_4(H) (1 + \eta \sin 2\theta)$. The coefficient $c_4(H)$ and the angular contrast η were treated

FIG. 6: Field directional dependence of the heat capacity of sample A at 2 K and 0.6 T. The field angle is measured with respect to the a -axis. The top panel shows the total heat capacity (open circles) and the 2-fold component, $C_2(\theta)$ relative to baseline of 4.9 (dashed line). The bottom panel shows the same data after subtraction of the 2-fold and lattice contributions, $C_4 = C_{\text{total}} - C_2(\theta) - C_0$. The data were best described by a cusped function, $C_4(\theta; H) = c_4(H) (1 + \eta \sin 2\theta)$ with $c_4 = 1.45$ and $\eta = 0.0415$.

as field dependent fitting parameters. The solid line in the lower panel of Fig. 6 shows the fit with $\eta = 0.0415$ at 0.6 T. The sharp minima along $\langle 100 \rangle$ indicate that there exist gap minima or nodal structures along those directions. The nodal positions and the small oscillation amplitudes are consistent with previous reports of $\text{YNi}_2\text{B}_2\text{C}$.^{15,30} The field-angle heat capacities of sample C and N at low fields are essentially the same as that of sample A.

Figure 7 gives 3D surface plots of the field-angle heat capacity of sample C at 2.5 K. The x-axis is the in-plane field direction with respect to the crystal axes and the y-axis is the applied magnetic field intensity in tesla. The z-axis is the four-fold heat capacity normalized by the Doppler-induced heat capacity: $C_4(H; \theta) = c_4(H) (1 + \eta \sin 2\theta)$. Figure 7(a) is a numerical calculation of the 3D nodal quasiparticle theory^{16,20} and Fig. 7(b) are the experimental results of sample C. In the quasiparticle theory, the only adjustable parameter is the Doppler-related energy $E_h(v)$ (see Eq. 1). In the numerical calculation, we used $a = 1$, the gap maximum $\Delta = 1.76 k_B T_c$, and the average Fermi i

FIG. 7: The 3D surface plots describe magnetic field-angle (x-axis) and field-intensity (y-axis) dependence of the in-plane specific heat ratio at 2.5 K: $C_4(H; \alpha)/C_4(H)$. Fig. (a) is a numerical calculation of the specific heat due to nodal quasiparticles in 3D system and Fig. (b) is the experimental data of the single crystal sample C. The experimental data were FFT low-pass filtered with a cut-off frequency of 0.03 Hz with angles being considered as time. Both plots (a) and (b) were constructed with 0.5, 1, 1.5, and 2 T data sets.

velocity $v = \frac{p}{m_a v_c} = 1.3 \times 10^7$ cm/sec. The extracted Fermi velocity is similar to that from the band structure calculation ($\frac{p}{m_a v_c} = 1.2 \times 10^7$ cm/sec).³⁵ The 3D plots of sample N show similar behavior to that of sample C requiring a larger Fermi velocity, i.e., $v = 1.5 \times 10^7$ cm/sec.²³ The larger value may be due to the uncertainty in determining the field-induced heat capacity.

In field-angle heat capacity measurements, there are three relevant energy scales, which are the Doppler energy scale E_h , the paramagnetic energy H , and the thermal energy of $k_B T$. In the mixed state, the paramagnetic

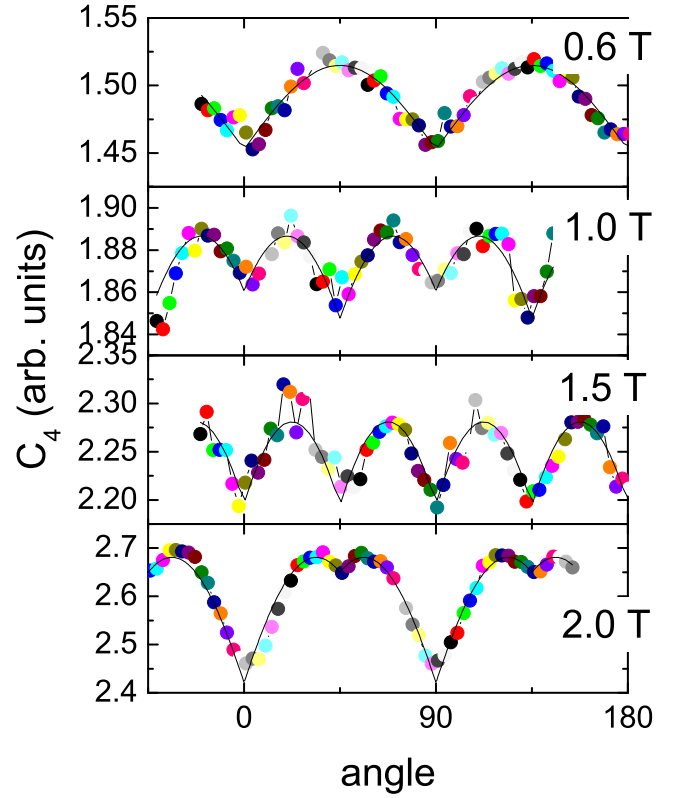

FIG. 8: Angle-resolved heat capacity of sample A at 2 K and a 4 + 4 pattern (solid line). The magnetic fields are 0.6, 1, 1.5, and 2 T, from top to bottom panel.

energy is of order 1 K and the Doppler energy scale is 10 K. The latter is much higher than the experimental temperature 2 K. Therefore, the Doppler effect on the nodal quasiparticles is dominant over the thermal and the paramagnetic effects in this regime, indicating that the 3D nodal quasiparticle theory of the Doppler effect is applicable as was evident from the reasonable agreement between experiments and the numerical calculations.

Figure 8 shows the heat capacity of sample A as a function of field angle at 2 K and 0.6, 1.0, 1.5, and 2.0 T from top to bottom panel. At 1 T, surprisingly, additional minima develop along $\langle 110 \rangle$, producing two sets of fourfold patterns or 8-fold, an effect not observed in either sample C or N with higher T_c 's. The crossover field from the fourfold to the (4 + 4) pattern of sample A lies between 0.6 and 1 T, which is also the point where the heat capacity of sample A deviates from the H dependence (see Fig. 5). With increasing field, the splitting gradually disappears and the field-angle heat capacity recovers its fourfold pattern above 4 T. We also measured the field-angle heat capacity of sample A at 4 K to check if the anomalous peak splitting persists at higher temperatures (Fig. 9). The fourfold pattern now persists to 1 T, evolving into two sets of fourfold patterns above 2 T. The 4 T data at 4 K have a shape similar to the 2 T data at 2 K. The crossover field H_{s1} increases with increasing

FIG. 9: Angle-resolved heat capacity of sample A at 4 K and a 4 + 4 pattern (solid line). The applied magnetic fields are 1, 2, 3, and 4 T, from top to bottom panel.

temperature.

It is worth noting that the anomalous 8-fold pattern occurs only at sample A, which has half the electronic mean free path of the sample N, while the T_c is slightly decreased. According to the nonlocal theory by Kogan et al.,³⁵ the hexagonal-to-square FLL transition depends on the electronic mean free path and the superconducting coherence length. Gamma et al. found that a mere 9% of Co doping onto the Ni site in Lu1221 can make the FLL transition field 20 times higher than that of the pure matrix for $H \parallel [001]$.⁴³ The FLL transition field for pure Lu1221 is around 0.2 T,⁴⁴ which is well below our measurement range, suggesting the nonlocal effects would not influence the field-angle heat capacity of purer samples. In contrast, the disorder in sample A increases the transition field to at least twice higher than that of sample N,⁴³ i.e., to a field relevant in the field-angle heat capacity measurement of sample A.

When the magnetic field is rotated within the ab-plane, the transition field may differ with different field directions because of the different nonlocal range, i.e., $\lambda = l$. The two different transition fields can be characterized by H_{s1} for $\langle 110 \rangle$ and H_{s2} for $\langle 100 \rangle$. As a magnetic field rotates within the ab-plane for $H_{s1} < H < H_{s2}$, the FLL will experience a structural change (or distortion), i.e. hexagonal for $H \parallel [100]$ and square for $H \parallel [110]$. Since the borocarbides have nodes on the

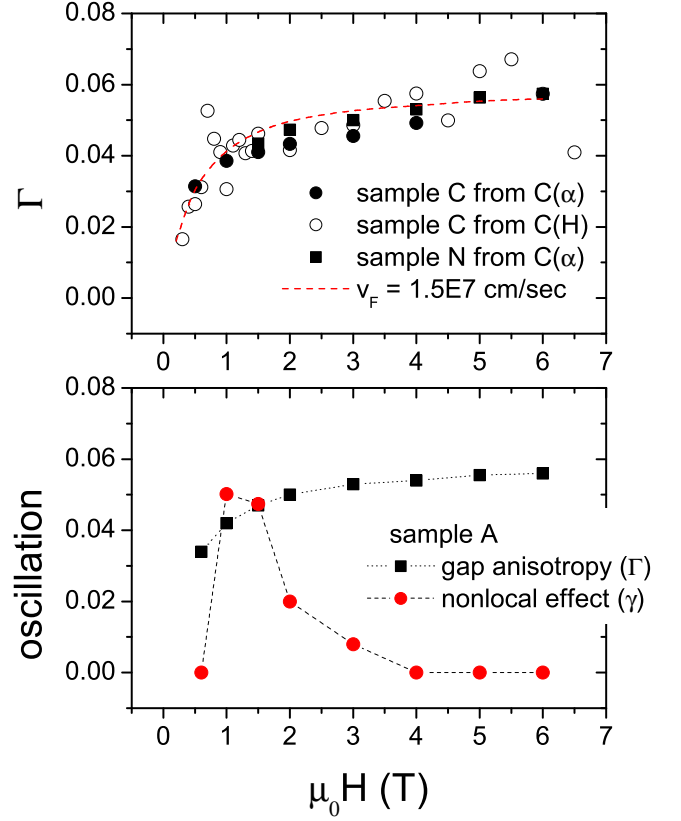

FIG. 10: Oscillation amplitude of sample C (circles) and sample N (squares). The dashed line is from the 3D nodal quasiparticle theory with $v_F = 1.5 \cdot 10^7$ cm/sec. The bottom panel contrasts the oscillation amplitude due to the nonlocal effects (circles) and gap anisotropy (squares).³⁸

Fermi surface, the DOS will differ depending on the FLL structure.⁴⁰ The negative deviation from the H above H_{s1} in the heat capacity of sample A (see Fig. 5b) also indicates that the DOS of the hexagonal FLL is larger than that of the square FLL. In addition to the anisotropic gap modulation,³⁰ the DOS will oscillate due to the FLL anisotropy, leading to a (4+4)-fold pattern.

When $H < H_{s1}$ or $H > H_{s2}$, the field-induced parameter c_4 can be considered as constant and the DOS oscillation is just from the gap anisotropy. When $H_{s1} < H < H_{s2}$, in contrast, c_4 is not independent of field direction any more, but oscillates due to the anisotropic FLL transition field: $q = p[1 + \sin^2(\phi - 45^\circ)]$. q has maxima along $\langle 100 \rangle$ and minima along $\langle 110 \rangle$. Then, the field-angle heat capacity can be written as

$$C_4(\phi) = p[1 + \sin^2(\phi - 45^\circ)](1 + \sin^2 \phi); \quad (4)$$

where p is a field-dependent fitting parameter. The value $\sin^2 \phi$ represents the oscillation due to gap anisotropy in pure samples (see Fig. 10). The nonlocal effects give rise to a 45°-shifted 4-fold pattern and are accounted for by $\sin^2(\phi - 45^\circ)$. The solid lines in Fig. 8 and 9 are least squares fits of Eq. (4) and represent the data very well. The oscillations due to the nonlocal effects (γ) and the gap

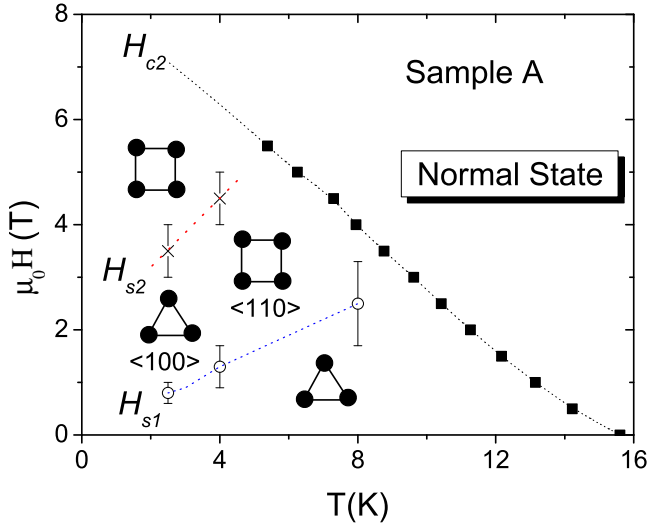

FIG. 11: $H-T$ phase diagram of sample A with lowest T_c . H_{s1} is the FLL transition for $H \parallel [110]$ and H_{s2} for $H \parallel [100]$. The dotted lines are guides to the eyes. Triangles and squares were sketched to show the corresponding FLL.³⁸

anisotropy (γ) at 2 K are compared as a function of magnetic field at the bottom panel of Fig. 10. The FLL effect

increases sharply above 0.6 T and decreases gradually to zero at 4 T, indicating that the low field corresponds to H_{s1} and the high field to H_{s2} . It is interesting to note that Miranovic et al. came to a similar conclusion by solving quasi-classical Eilenberger equation for nodal superconductors with anisotropic Fermi velocity.⁴⁵

The $H-T$ phase diagram of the disordered sample A is shown in Fig. 11. H_{s1} is the FLL transition field for $H \parallel [110]$ and H_{s2} , for $H \parallel [100]$. The increase in the transition fields with increasing temperature is consistent with the nonlocal prediction where the nonlocal range decreases with raising T .³⁵ The difference in the FLL transition fields for $H \parallel [100]$ and $H \parallel [110]$ can be due to the upper critical field H_{c2} anisotropy between the two directions. Since the effective nonlocal range is proportional to the coherence length ξ , the H_{c2} anisotropy leads to a higher FLL transition field for $H \parallel [100]$ than that for $H \parallel [110]$. The FLL transition occurs when the intervortex distance is comparable to the effective nonlocal radius. The observed ratio $H_{s2}/H_{s1} \approx 4$ is larger than the predicted ratio 2,³⁵ but is smaller than the reported ratio of 10 in YNi_2B_2C .³³ The difference between experiments and theory may attest to the need that we take into account both the nonlocality and the anisotropic gap nature of the borocarbides.

IV. CONCLUDING REMARKS

We reviewed the first direct evidence for a variation of the DOS of nodal quasiparticles (nqp's) of unconventional superconductors $Lu(Y)Ni_2B_2C$. The four-fold

field-angle oscillation in the heat capacity of the borocarbides is due to the nqp's experiencing a field-induced Doppler energy shift. The 3D superconductivity of the borocarbides is reflected in the small oscillation amplitude of 4 %, not 40 % expected for 2D superconductors. A dramatic change has also been observed in a slightly disordered $Lu1221$. A fourfold pattern in $C(\theta)$ changed to an eightfold or two sets of fourfold pattern at the FLL transition field, evidencing that both nonlocal effects and an anisotropic superconducting gap coexist in the borocarbides.

Even though it is clear that there are nodes along $<100>$ directions in the borocarbides, the type of nodes has yet to be answered. Based on a theoretical calculation,⁴⁶ it is asserted that the rapid decrease of the oscillation amplitude of the angle-dependent thermal conductivity with polar angle is due to a point node gap located along $[100]$.¹⁵ Miranovic et al., however, claimed that the oscillation amplitude decreases sharply with field for both vertical line node and the $s+g$ point node cases, suggesting that the conical field rotation experiments may not be able to distinguish the two cases.⁴⁵ In order to determine the precise gap structure, instead, they suggested the field dependence of the oscillation amplitudes at low fields. The oscillation monotonically decreases with increasing field for point nodes, while it has a maximum for line nodes. We plan to measure conical field-angle heat capacity and extend our measurements to lower fields, which could shed more light on the controversy of the nature of nodes. A systematic study on disorder effects through Co doping on Ni site, $LuNi_{1-x}Co_xB_2C$, will clearly elucidate the correlation between nonlocal effects and anisotropic gap effects.

It is gratifying that other field-angle heat capacity have been followed after our pathbreaking work.³⁰ Deguchi et al. applied the technique to the spin-triplet superconductor Sr_2RuO_4 and found a fourfold oscillation for $H \parallel c$ axis, providing decisive information on the multi-band superconductivity and gap structures.⁴⁷ Aoki et al. have studied the heavy-fermion superconductor $CeCoIn_5$ and found a clear fourfold oscillation in $C(\theta)$ with minimum along $<100>$, suggesting the presence of line nodes at those directions.⁴⁸ Their interpretation of the superconducting gap symmetry as d_{xy} wave, however, contradicts that $(d_{x^2-y^2})$ by thermal conductivity data.⁴⁹ It is interesting to note that the angle-resolved specific heat directly measures the zero-energy density of states (ZEDOS). On the other hand, the thermal conductivity data (κ) necessarily involve both the ZEDOS and the quasiparticle scattering time (τ),¹¹ making it difficult to identify the gap node direction in some cases.

Finally, we mention that the angle-resolved specific heat measurement opened a new venue to better understanding unconventional superconductivity. Even though only a few classes of unconventional superconductors have been studied by this technique,^{30,38,47,48} new features on their superconducting properties have been revealed, indicating a whole new aspect of superconductiv-

ity may await to be found.
