(Received April 14, 2024)

W e investigate ground-state properties of a one-dimensional S = 1 spin-orbital model with or without uniaxial single-ion anisotropy. By means of the density matrix renormalization group method, we compute the ground-state energy, the magnetization curves and the correlation functions. We discuss how the ground-state properties depend on the two exchange couplings for orbital and spin sectors. The phase diagram obtained is compared with that for the S = 1=2 model. We also address the elect of uniaxial single-ion anisotropy.

KEYW ORDS:S = 1 spin-orbitalm odel, one dimension, uniaxial single-ion anisotropy,

x1. Introduction

The interplay of spin and orbital degrees of freedom has provided a variety of interesting phenom ena in correlated electron system s. To understand the role played by spin and orbital uctuations, several di errent spinorbital models have been studied extensively. As the sim plest exam ple among others, the one-dimensional (ID) spin-orbital model with SU (4) symmetry, which describes a spin-1/2 system with two-fold orbital degeneracy, has been investigated.^{1,2,3,4)} A slightly extended model, the 1D spin-orbital model with SU (2) SU (2) symmetry,^{5,6,7,8)} has also been studied and the groundstate phase diagram has been established, which consists of a variety of phases including gapful/gapless spin and orbital phases, etc.

Some transition m etaloxides such as m anganetes and vanadates, for which the H und coupling plays an important role, have higher spins with degenerate orbitals. This naturally motivates us to extend the above spin-orbital model to a model possessing higher spins. A speci c generalization of the model to the S = 1 case has been proposed for vanadates, such as YVO₃, and investigated in detail.^{9,11,13,10,12)} In particular, the competition of the orbital-valence-bond (OVB) solid phase and spin-ferrom agnetic phase has been clari ed, in accordance with some experimental notings in the low-tem perature quasi-1D phase of YVO₃. The realization of the OVB phase has been suggested in neutron di raction experiments.¹⁴

M otivated by the above hot topics, we study an SU (2) SU (2) extension of the S = 1 spin-orbitalm odel in 1D. In contrast to them odelproposed for YVO₃,⁹⁾ our aim is to capture generic features inherent in the S = 1 spin-orbital m odel, which is to be compared with the S = 1=2 m odel^{1,3,4,5,6,7,8)} W e also take into account the e ects of single-ion anisotropy, which may play an important role for S = 1 system s. W e exploit the density

m atrix renorm alization group (DMRG) m ethod¹⁵⁾ and investigate quantum phase transitions. By calculating the ground state energy and the spin/orbital correlation functions for a given strength of single-ion an isotropy, we obtain the phase diagram in the plane of two exchangecoupling constants for spin and orbital sectors.

This paper is organized as follows. A fiter a brief explanation of the model in the next section, we present the DMRG results in x 3 for the ground-state energy, the spin/orbital magnetization curves and the correlation functions, from which we determ ine the phase diagram. In x 4, we address the e ects of uniaxial single-ion anisotropy. A brief sum mary is given in x 5.

x2. M odel

W e consider an S = 1 extension of the 1D spin-orbital model with uniaxial single-ion anisotropy D, which is characterized by two coupling constants A and B related to the spin and orbital degrees of freedom. The H am iltonian reads

$$H = J \qquad (S_{i} \quad S_{i+1} + A) \quad T_{i} \quad T_{i+1} + \frac{B}{4} + D \qquad (S_{i}^{z})^{2}; \qquad (1)$$

where S_i is an S = 1 spin operator at the i-th site and T_i is a T = 1=2 pseudo-spin operator acting on the doublydegenerate orbital degrees of freedom . J controls the m agnitude of the exchange couplings, which will be taken as the energy unit in the following discussions. The D term represents uniaxial single-ion an isotropy, which has been discussed in detail so far in the H aldane spin chain system s.

At a special point (A = B = 1 and D = 0), the symm etry is enhanced to SU (2) SU (2). It is known that the ground state in this case is the orbital liquid with a sm all spin gap, which is called the OVB solid state.^{10,9,11,12,13}</sup> A ctually, the special model studied by K haliullin et al. for cubic vanadates^{9,11,12,13} includes the above special case, at which our model coincides with theirs.

E-m ail: satoshi@ tp.ap.eng.osaka-u.ac.jp

Them odel (1) is regarded as a natural extension of the 1D S = 1=2 spin-orbitalm odel with SU (2) SU (2) sym - metry, $^{1,3,4,5,6,7,8)}$ for which the D -term is absent, and A ! A=4 for the spin (S = 1=2) part. The comparison of these two models may allow us to clarify the role of spin uctuations on the spin-orbitalm odel.

x3. G round State P roperties w ithout A n isotropy

In this section, we investigate the ground-state properties of the Ham iltonian (1) with D = 0, and determ ine the zero-tem perature phase diagram. We rst notice that the spin- (orbital-) ferrom agnetic state should be the ground state for B ! 1 (A ! 1). Therefore, when we calculate the ground-state energy of the spin-(orbital-) ferrom agnetic state, we can $x hS_i \quad S_{i+1}i = 1$ (hT i $T_{i+1}i = 1=4$).

Fig. 1. The energy per site as a function of the exchange parameter B for A = D = 0; the ground-state energy obtained by the DMRG is shown by triangles. We also plot the energy computed for the spin-ferrom agnetic state (circles) and the orbital-ferrom agnetic state (squares). We clearly see two cusp structures, indicating rst-order phase transitions. The interm ediate region is identied as the OVB solid state.

In Fig. 1, the energy obtained by the DM RG is shown as a function of B with keeping A = 0 xed. We nd two rst-order transition points; B_{c1} ' 0:09 and B_{c2} ' 0:41. As clearly seen in Fig. 1, the system favors the spin-ferrom agnetic state for small B (< B_{c1}), but stabilizes the OVB solid state⁹ for the interm ediate region (B_{c1} < B < B_{c2}). For large B (> B_{c2}), the ground state is in the orbital-ferrom agnetic phase.

By repeating sim ilar estim ations of the critical points for other choices of A, we determ ine the ground-state phase diagram for D = 0 in the A-B plane, which is shown in Fig. 2. The phase diagram consists of four phases; the OVB phase (I), the spin-ferrom agnetic phase (I), the orbital-ferrom agnetic phase (II), and the spinferro/orbital-ferrom agnetic phase ($\mathbb V$). $\mathbb W$ e can estim ate the phase boundary exactly in several limiting cases. First, by dropping the spin (orbital) degrees of freedom when the spin- (orbital-) ferrom agnetic ground state is stabilized, we immediately nd that the phase boundaries of I-V and II-V are exactly given by A =1 and 1, respectively. We can also determ ine the ex-B = act asym ptotic behavior of the boundary. The boundary between the phases I and I approaches $B = 4j_q^{(1=2)}j_q$ for A ! 1, where $q^{(1=2)} =$ log 2 + 1 = 40:443 is

the exact ground-state energy for the isotropic T = 1=2 H eisenberg chain.¹⁶⁾ On the other hand, for B ! 1, the I-II boundary approaches A = $j_g^{(1)}j_g$ where $g^{(1)}$

1:401484 is the ground-state energy for the S = 1 H aldane chain.¹⁵⁾ T his asym ptotic analysis is consistent with our phase diagram obtained here num erically.

Fig. 2. Phase diagram of the 1D S = 1 spin-orbitalm odel in the A-B plane without uniaxial single-ion anisotropy. The phase I is the OVB phase (see text). In the phase I, the spin part is in the fully polarized state while the orbital part form s the gapless antiferrom agnetic T = 1=2 H eisenberg chain. On the other hand, in the phase II, the orbital sector is in the ferrom agnetic phase while the spin sector is in the S = 1 H aldane phase. B oth of the spin and orbital parts are in the fully polarized ferrom agnetic states in the phase V. All the transitions are of rst order.

Fig. 3. Spin (upper panel) and orbital (low er panel) correlation functions in the phase I along the A = B (= x) line in the OVB phase. The site index i is even (odd) for open circles (solid triangles). The even-odd i-dependence re ects a dim er property of the OVB phase. W ith increasing x, the dim erization gets strong and the size of a gap becom es large.

A lthough characteristic properties of the phases I, II and V can be directly deduced from those of the S = 1=2;1 chains, there appear nontrivial properties due to the interplay of spins and orbitals in the OVB phase I. W e thus calculate the short-range spin and orbital correlation functions by taking the line A = B (= x) as representative parameters in the OVB phase.

The results are shown in Fig. 3. As x increases, the even-odd i-dependence of the correlation functions gets

Fig. 4. Spin (a) and orbital (b) m agnetization curves at A = B = 1 (solid line) and 0.5 (dashed line). We calculate the spin (orbital) m agnetization by setting $h_o = 0$ ($h_s = 0$). Note that both of the spin and orbitalm agnetizations exhibit typical behavior of gapful system s, although the orbital gap is much larger than the spin gap. For higher elds, the spin and orbital magnetizations show the rst-order phase transition to the fully polarized state, which is signaled by a discontinuous jump.

stronger both for spin and orbital sectors, in plying that the system favors the dimerization. At x = 1, the orbital sector forms nearly perfect dimer singlets. i.e. hT_i T_{i+1}i 3=4 for even i, while it is almost zero for odd i. On the other hand, two adjacent spins are almost parallel for even i, i.e. hS_i S_{+1} i 1, while for odd i, there are weak antiferrom agnetic correlations. These properties clearly characterize the dimer-like nature of the OVB phase.^{9,11,13} It is remarkable that even if x decreases from unity, the orbital correlation hT_i T_{i+1}i for odd i stays very small, indicating that the orbital sector can be regarded as an assembly of approximately independent dimers irrespective of the values of x.

In order to observe the properties of the phase I in more detail, we compute the spin/orbitalm agnetization. To this end, we add the following terms to the Ham iltonian (1),

$$H_{ex} = h_s S_i^z h_o T_i^z; \qquad (2)$$

where h_s and h_o are external elds conjugate to the spin and orbital magnetizations. The calculated magnetization curves are shown in Fig. 4 for two typical choices of the exchange couplings. Let us rst observe the spin magnetization for x = A = B = 1 shown in Fig. 4 (a). The magnetization hS_1^z is zero in small elds, in accordance with the existence of a spin gap in the OVB phase. After the spin gap disappears at very low elds, the magnetization increases smoothly, and jumps at the second critical point (e.g. $h_s = 0.122$ for x = 1), driving the system to the spin-ferrom agnetic state via a rst-order transition. Similarly, the orbital magnetization shown in Fig. 4 (b) indicates that the OVB state with $hT_1^z i = 0$ is favored in small elds, and then the

orbital magnetization HI_{i}^{z} i develops gradually beyond a critical eld corresponding to the orbital gap. The system further undergoes a rst-order transition to the orbital-ferrom agnetic state. C om paring the spin and orbital gaps, we notice that the orbital gap is much larger than the spin gap,^{11,13} consistent with the results for correlation functions, where the orbital-dimerization is quite strong. In contrast to the low - eld behavior, both spin and orbital degrees of freedom change their characters at the rst-order transition points. Note that the resulting high-eld phase with the fully spin (orbital) polarized state is the same as the phase II (III).

Fig. 5. Phase diagram of the S = 1=2 spin-orbital model.^{5,6,7,8)} Phase I is a gapful phase with doubly degenerate ground states which form alternating spin and orbital singlets. In the phase I, the spin degrees of freedom are in the fully polarized ferrom agnetic state while the orbitals are in the antiferrom agnetic ground state and vice versa in the phase II. Both spin and orbital degrees of freedom are in the fully polarized ferrom agnetic states in the phase V. The phase V is a gapless phase including an integrable SU (4) point (A = B = 1).

Before closing this section, we compare the present phase diagram with that for the S = 1=2 spin-orbital model^{5,6,7,8)} which is sketched in Fig. 5. The corresponding spin-orbital Ham iltonian is given by (1) by putting S = 1=2 and replacing A with A=4 for the spin sector. O verall features are similar both in S = 1 and 1=2 models: the phases I, II and V are respectively characterized by the spin-ferro/orbital-singlet state, the spin-singlet/orbital-ferro state and the spinferro/orbital-ferro state. The phase I also exhibits sim ilar dim er-like properties in both cases. A rem arkable di erence is the gapless phase V realized in the S = 1=2model around the SU (4) point. This phase, which is stabilized by enhanced quantum uctuations both in spin and orbital degrees of freedom, disappears in the $S = 1 \mod U$ we think that the phase V is inherent in the S = 1=2 case, and a higher-spin extension of the SU (2) SU (2) m odel m ay have a phase diagram similar to the present S = 1 case.

In contrast to the $S = 1=2 \mod d$, the single ion anisotropy plays an important role for the $S = 1 \mod d$, which may provide a rich phase diagram. This problem is addressed in the following. x4. E ects of U niaxial Single-Ion A nisotropy4.1 D < 0

Let us now consider the e ects of uniaxial single-ion anisotropy. We start with the ground-state properties for the case of D < 0.

Recall that in the phases I and V in Fig. 2, the spin sector is in the fully-polarized state, so that the nature of these phases may not be altered upon the introduction of D < 0, except that the direction of spin ordering is now xed to the z-axis. On the other hand, the negative D suppresses quantum uctuations in the spin-gap phases I and II, resulting in the antiferrom agnetic spin order with Z_2 symmetry breaking. We refer to the corresponding

new ordered phases as the phase I_{m} and ${\rm I\!I}_{m}$, respectively. Note that di erent types of spin order should em erge in the phases I_m and II_m . The spin-antiferrom agnetic order has the 4-site period (up-up-down-down alignment) in the phase I_m , and the 2-site period (up-dow n-up-dow n alignment) in the phase \mathbb{II}_m , as schematically shown in Fig. 6. This di erence com es from the ground-state properties without an isotropy. Namely, in the OVB phase I, spins favor a ferrom agnetic con guration in a orbital-dim er singlet and an antiferrom agnetic con guration between adjacent orbital singlets, so that the spin sector is described by an e ective ferro-antiferrom agnetic bond-alternating chain. On the other hand, in the phase II_m , the spin sector form s the S = 1 H aldane state at D = 0, so that it naturally leads to an ordinary antiferrom agnetic order upon the introduction of D < 0.

Fig. 6. Schem atic description of spin orders for the phases I_m and \mathbb{II}_m . The labelS (T) denotes the spin (orbital) part, respectively.

The above tendency to spin ordering is indeed observed in the nearest-neighbor correlation functions shown in Fig. 7 as a function of D (< 0). We exploit two typical values of A and B, which correspond to the parameters for the phases I and II at D = 0. Even in the presence of D, both spin and orbital correlation functions show (do not show) the even-odd i-dependence for the parameters corresponding to the phase I_m (III_m). It should be also noticed that the orbital correlations are alm ost independent of D, as should be naively expected: alm ost isolated orbital-dim er states are favored in the phase I_m , while the orbital sector is always in the fully polarized state, hT i $T_{i+1}i=1=4$, in the phase I_m .

As m entioned above, the spin-antiferrom agnetic order

Fig. 7. Spin (upper and m iddle panels) and orbital (low er panel) correlation functions as a function of D : A = B = 1 (solid circles : i = odd and open circles : i = even) and A = -1, B = 1 (open squares).

with the 4 (2)-site period should be stabilized beyond a certain critical value of ${\rm p}$ jin the phase I_m (${\rm I\!I}_m$). Therefore, spin uctuations are suppressed and thus the correlation hS_i^z ${\rm spin}_{i+1}i$! 1 while hS_i^+ ${\rm spin}_{i-1}i$! 0 as ${\rm p}$ j increases. We now determ ine the phase transition point for II! ${\rm I\!I}_m$. Note that the orbital sector always orders ferrom agnetically, so that the Ham iltonian (1) for the spin sector is reduced to

$$H_{OF} = J_{i}^{O} (S_{i} \quad S_{i+1} + A) + D_{i}^{X} (S_{i}^{z})^{2}; \quad (3)$$

with $J^0 = J(1 + B)=4$. In this case, the competition of the single-ion anisotropy D and the elective exchangecoupling J^0 results in the following transition, which is independent of A. A coording to the results for the isotropic S = 1 chain,^{17,18,19,20} the ground state is in the Haldane phase for $0.35J^0$ D J^0 , and in the N eel phase for D < $0.35J^0$. Therefore, the critical value is given by D_c = 0.175J in Fig. 7, which separates the Haldane phase and N eel phase for the spin sector.

It is more di cult to determ ine the boundary between I and I_m only from our data for the correlation functions in Fig. 7, partially because the spin gap is very small in the phase I. Nevertheless, by taking into account that the spin gap is much smaller than the orbital gap (Fig. 4), we reasonably expect that the corresponding critical value of D, which separates I and I_m in Fig. 7, may be quite small, say, less than 0:1. The precise critical value should be obtained by exploiting in proved num ericalm ethods, which we wish to leave for the future study.

We show the phase diagram in the A-B plane for D < 0 in Fig. 8. Since the transition from the OVB phase to the other phases is of rst order, we determ ine the corresponding boundary by comparing threetypes of the energy am ong the OVB solid state, the spinferrom agnetic state and the orbital-ferrom agnetic state. As m entioned above, the phase boundary between the phases \mathbb{I} and \mathbb{I}_m is given by

$$B_{c}$$
 ' 11:4D 1; (4)

which is independent of A. For example, B_c ' 0:14 for D = 0:1, as shown in Fig. 8(a). In the case of D = 1:0 in Fig. 8(b), the phase II_m dominates the phase II in the displayed region, because the boundary between these two phases is at B_c ' 10:4 for D = 1:0. Note that the orbital sector orders ferrom agnetically for all D in the phases II, II_m and V. As mentioned above, the spin state in the OVB phase I is sensitive to D, so that the ordered phase I_m dominates the phase I both for D = 0:1 and 1:0 in the region shown in Fig. 8

Fig. 8. Phase diagrams for D < 0: (a)D = 0:1 and (b)D = 1:0. The phases labeled as I, II and IV are the same as in Fig.
2. Im and IIm are spin-ordered phases (see text). The solid lines except for the III-IIm boundary represent rst-order transitions. For reference, the phase boundary at D = 0 is shown by the dashed lines.

4.2 D > 0

Let us now move to the positive D case. We start with the phases II and V, for which the phase transition points are easily determ ined, since the orbital sector is in the fully polarized state. In the phase II, the so-called large-D phase is stabilized in the spin sector for D > $J^0 = J(1 + B)=4$; i.e. for $1 < B < B_c$ ($B_c = 1 + 4D$), the large-D phase appears, while the H aldane phase persists for B > B_c . On the other hand, in the phase IV, the XY phase em erges^{18,21,22)} in the region 1 4D < B < 1 in the presence of the D-term.

It turns out that the boundary between the phases I and I is quite sensitive to positive D, and exhibits som ewhat complicated features. This is contrasted to the robust rst-order transition between the phases I and II, which hardly changes its character as far as D is sm all. To make the above point clear, we observe the behavior of the correlation functions by choosing D = 0.01 with two typical values of A = 0 and 0.5. In Fig. 9 (a), the B-dependence of the spin and orbital correlation functions are shown for A = 0. For sm all B, the ground state is in the phase I, so that both spin and orbital correlation functions are spatially uniform without the even-odd i-dependence. W ith increasing B, a continuous quantum phase transition occurs from the phase I 0:1, in contrast to the rst-order transito I at B _c tion at D = 0, as seen in Fig. 9(a). Beyond the critical value B $_{\rm c}$, the spin and orbital correlation functions exhibit the even-odd i-dependence, re ecting dim er properties of the OVB solid state. Unfortunately, we cannot gure out whether this continuous transition is Berezinskii-Kosterlitz-Thouless (BKT) type^{23,24,25)} or not only from the results shown in Fig. 9, because an extrem ely large system size is necessary to obtain the sensible results in our spin-orbitalm odel with a tiny spin gap. Nevertheless, we can discuss som e characteristic properties of each phase from the correlation functions. First, we note that the spin sector in the phase I may be changed to the XY phase upon introduction of D.^{18,21,22)} This can be inferred from the spin correlation functions shown in Fig. 9, which indeed show the preference of the XY phase: $hS_i^+S_{i+1}i = 1$ and $hS_i^zS_{i+1}^zi$ 0. This observation is also supported by the following consideration. Note rst that the orbital correlation function is not affected by D in the phase I, and takes the constant value hT_{i} $T_{i+1}i$ $g^{(1=2)}$ characteristic of the T = 1=2 orbital chain, so that we can focus on the remaining S = 1 spin part. According to the isotropic S = 1 ferrom agnetic $\operatorname{chain}^{18,21,22}$, the rst-order phase transition from the spin-ferrom agnetic phase to the XY phase occurs upon introducing D, which is consistent with our num erical results for the correlation functions.

Fig. 9. Spin (upper and m iddle panels) and orbital (low er panel) correlation functions for D = 0:01 as a function of B ((a) A = 0:0, (b) A = 0:5). The site index i is even (open circle) or odd (solid circle). The even-odd i-dependence re ects dim er properties of the phase I.

The above continuous transition is in contrast to that for A = 0.5 shown in Fig. 9 (b), where the system exhibits the rst-order phase transition accompanied by a clear jump at B_c 0.2 both in the spin and orbital correlation functions. This characteristic behavior is essentially the same as that for D = 0.

By examining the correlation functions for other

choices of A, we end up with a phase diagram expected for D = 0.01, which is shown in Fig. 10. The phase boundary between the phases I and II is either continuous or rst-order depending on the value of A: the transition is continuous (rst-order) for A < 0.1 (A > 0.1). We have checked that the critical value of A, which separates these two types of transitions, increases m onotonically with the increase of D. For example, the critical value is A = 0.5 for D = 0.012. For small D, the rstorder transition dom inates m ost part of the I-II phase boundary.

Here, an important question arises: what really causes the change in the nature of the transitions, rst-order or continuous, on the I-II phase boundary. To address this question, we should go into the detail of the phase I. Since the orbital part always forms the dimerized state in the phase I even for nite D, we again focus on the spin sector. Recall here that the spin sector in the OVB phase I form s the state similar to the S = 2Haldane-gap state (same universality class).^{10,11)} Fortunately, the 1D S = 2 Haldane system with uniaxial single-ion anisotropy was already investigated.^{26,27)} Schollwock num erically checked the disappearance of the spin gap at a very small critical value of D (0:02J), and the system enters the "interm ediate-D phase", which was claim ed to be equivalent with the XY-phase.²⁷⁾ Imm ediately after the above analysis, O shikaw a found that the behavior of the string correlation in z-axis deviates from a simple power-law, as a result, he suggested that this interm ediate-D phase is not truly gapless XY phase, but som ew hat modied one with som e anom alous properties in the z-com ponents.²⁶⁾ A nyw ay, the m essage from the above analysis is that the introduction of sm all positive D changes the Haldane phase to the so-called interm ediate-D phase. In our model, the size of the spin gap in the phase I gets sm all as A ! 1 and B ! 1 (Fig. 4). Therefore, we think that the spin sector in the OVB phase is changed to the "interm ediate-D type phase" in the region with sm all A and B, while the original spin-gap state in the OVB phase can still persist for larger A and B. This may cause the change in the nature of the phase transition on the I-I phase boundary. Unfortunately, our num erical calculation is not powerful enough to draw a de nite conclusion about the existence of the "interm ediate-D type phase". We would like to clarify the detail in the future work.

x5. Sum m ary

W e have investigated quantum phase transitions of the 1D S = 1 spin-orbital model with uniaxial single-ion anisotropy. By m eans of the DMRG method, we have calculated the ground-state energy, the spin/orbitalm agnetizations, and the correlation functions, from which we have determ ined the zero-tem perature phase diagram.

In the absence of the anisotropy, there appear four phases including the OVB phase characteristic of the S = 1 spin-orbital system .⁹⁾ This phase has a sm all spin gap and a fairly large orbital gap. In comparison with the S = 1=2 spin-orbital model, we have found that most of the phase diagram shows similar properties, but the

Fig. 10. Phase diagram for the model with D = 0:01. The solid lines (with dots) indicate the rst-order transition. Concerning the phase boundary between I and I, there is a continuous transition (broken line) for A 0:1, and a rst-order transition (solid line with dots) for A > 0:1. The interm ediate-D phase is expected to emerge in the spin sector of the OVB phase for sm allA and B. Note also that around the boundary of B = 1, there appear two new spin phases: the large-D phase (XY spin phase) in the tiny region 1 < B < 0:96 (1:04 < B < 1), although not shown explicitly in the gure (see text).

phase V inherent in the S = 1=2 m odeldisappears in the S = 1 case. We believe that a higher spin extension of the model should have the phase diagram similar to that of the present S = 1 m odel.

The introduction of uniaxial single-ion anisotropy D gives rise to some interesting aspects. For negative D, two di erent types of magnetic orders appear, depending on whether the system at D = 0 is in the orbital-ferrom agnetic phase or the OVB phase. Since the spin gap for the OVB phase is much smaller than that for the orbital-ferrom agnetic phase, the spin order in the OVB phase is induced even in the small p j region.

On the other hand, it has turned out that the situation is much more subtle in the positive D case. In particular, the phase transition between the OVB phase I and the spin-ferrom agnetic phase I exhibits som ew hat com plicated feature: the nature of transition changes from

rst-order to continuous one, depending sensitively on the value of D. A lthough we have not been able to obtain the precise phase diagram, som e characteristic properties of each phase have been discussed on the basis of the correlation functions. These nontrivial properties originate from interplay of the spin and orbital degrees of freedom, which m ay exem plify interesting aspects of the spin-orbital system s. Further investigations should be done in the future study, especially for the positive D case.
