Abstract

Surface x-ray scattering m easurem ents from several pure liquid m etals (H g, G a and In) and from three alloys (G a-B i, B i-In, and K -N a) with di erent heteroatom ic chem ical interactions in the bulk phase are reviewed. Surface induced layering is found for each elemental liquid metal. The surface structure of the K-N a alloy resembles that of an elemental liquid metal. Surface segregation and a wetting Im are found for G a-B i. B i-In displays pair form ation at the surface.

I. LIOUID METALS AND SURFACE INDUCED ORDER

Liquid metals (LM) are comprised of charged ion cores whose Coulomb interactions are screened by a conduction electron sea. At the liquid-vapor interface, this screened Coulomb potential gives way to the weaker van der W aals interactions that prevail in the vapor. Since the potential changes so substantially across the interface, the potential gradient is high, producing a force that acts on the ions at the liquid surface as though they were packed against a hard wall. A nalytic calculations and molecular dynamics simulations predict that atoms at the LM surface are stratified in layers parallel to the interface. By contrast, a monotonic density profile is predicted for the vapor interface of a nonmetallic liquid.

Observation of surface layering in LM requires an experimental technique sensitive to the surface-normal density prole that can resolve length scales of $2{3A}$. Specular X-ray rejectivity provides the most direct probe of the surface normal structure. X-rays incident on the liquid surface at an angle are scattered at the same angle within the rejection plane defined by the incident beam and the surface normal (Fig.1(a)). The rejected intensity is directly related to the surface normal density projection.

$$R (q_z) / q_z^2 (0 \sim (z) = 0 z) \exp(iq_z z) dz^2$$
: (1)

Since $@\sim(z)=@z$ is nonzero only near the surface, x-ray re ectivity is sensitive to the surface-normal structure and not to the structure of the bulk liquid. For example, surface layering with a spacing d produces a quasi-Bragg peak in the re ectivity, centered at the surface-normal momentum transfer $q_z = (4 =) \sin 2 = d^{2,3,4}$.

Grazing incidence direction (G \mathbb{D}) is sensitive to the in-plane structure of the surface. The in-plane m om entum transfer q_k is probed by varying the azim uthal angle 2 at xed. This geometry is surface sensitive when the incident angle is kept below the critical angle for total external rejection, g_k , thereby g_k thereby g_k is probed by varying the azim uthal angle 2 at xed.

For these structural studies it is essential to maintain a liquid metal surface that is at and clean on an atom ic scale. The sample is contained either in an ultra high vacuum (UHV) environment, or under a reducing atmosphere such as dry hydrogen gas, to prevent oxidation. For low vapor pressure, UHV-compatible metals such as Ga, Bi, and In, argon ion sputtering is possible, and this is the most reliable way to produce an atom ically clean surface⁴.

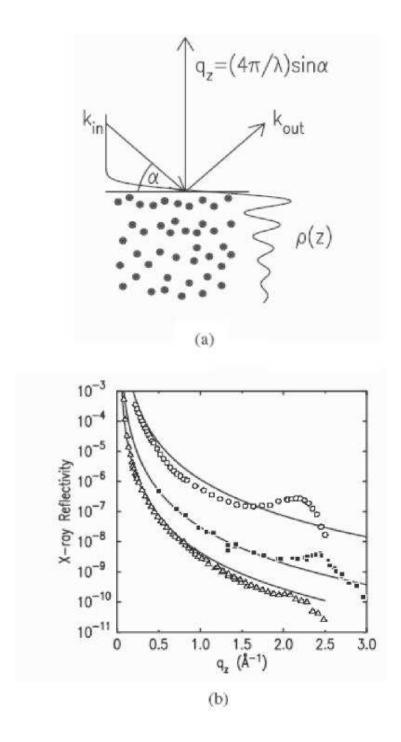

FIG. 1: (a) X-ray re ectivity geometry for the liquid metal, with layering of ions producing an oscillatory density pro le (z). (b) X-ray re ectivity for liquid Hg (35 C,), Ga (+25 C) and In (+170 C, 4). Solid lines: calculated Fresnel re ectivity from a at surface. Data for Ga and In are shifted for clarity.

Surface layering in elemental LM was rst experimentally con rmed by synchrotron x-ray re ectivity measurements of liquid H $\,g^3$ and G $\,a^4$. Experiments on In 6 and a number of alloys 7,8,9,10 followed. Fig. 1(b) shows experimental rectivities for three low melting point elemental LM. The principle deviation from the Fresnel rectivity calculated for a perfectly at metal surface (solid lines) is in the broad quasi-Bragg peak centered near $q=2.2\,\mathrm{A}^{-1}$. These rectivity proles can be well described by layered density proles decaying over several layers, shown schematically in Fig. 1(a).

II. SURFACE STRUCTURE OF BINARY LIQUID ALLOYS

In binary alloys properties such as atom ic size, surface tension, and electronic structure can be varied and should a ect the details of the surface structure, thus allowing a more systematic understanding of surface layering. Also, since binary alloys form various ordered phases in the bulk, another interesting question arises: How does the alloy's bulk phase behavior manifest itself at the surface, where the electronic structure, atom ic coordination and local composition are dierent? This question has motivated a number of studies on alloys, which have found that in general, surface layering competes with the formation of more complicated surface phases. For example, in miscible alloys the Gibbs adsorption rule predicts that the species having the lower surface energy will segregate at the surface. Observations on Ga-In⁹, Ga-Sn⁸ and Ga-Biat low Biconcentrations^{7,10} have found that surface segregation coexists with surface layering. In these alloys the rst surface layer is almost entirely composed of the lower surface tension component (In, Sn or Bi). By the second or third atom ic layer, the bulk composition has been reached. In the following sections, we describe recent x-ray results from alloy surfaces which demonstrate a range of dienent surface induced structural elects.

$A \cdot K - N a$

A Ikalim etals have a simple electronic structure which can be described by ideal Ferm i surfaces, and are soluble in each other with only a weak tendency towards phase form ation. Since alkalim etals have a very low surface tension, surface uctuations are enhanced. These properties are expected to make the alkalim etals surface structures dierent from those

of the main group metals studied so far. Ideally alkalimetals would be investigated under UHV conditions due to their high reactivity. However, at the melting point their high vapor pressures precludes this. By contrast, the melting point of the cutectic $K_{80}N_{80}$ alloy is su ciently low to allow UHV conditions. Due to the almost identical electron densities of the two components, when probed by x-rays this alloy exhibits the structure of a homogeneous liquid metal. Here we present preliminary results for the cutectic $K_{80}N_{80}$ alloy.

Fig. 1(a) shows the x-ray re ectivity from $K_{80}N$ a₂₀ along with the predicted re ectivity assum ing capillary wave roughness (G aussian form) of 12 and 1.5 A ¹¹. At all q, the re ectivity is bounded by these two curves; at lower q, it is better described by the 1.5 A roughness. On length scales $^{>}$ 6 A no obvious structural feature is found beyond the predicted capillary wave roughness. The low surface tension (120 dyn=cm) and the subsequently high roughness, appears to preclude measurements to q, large enough to directly observe a surface layering peak. This is in contrast to well-de ned surface layering peaks observed for Ga, Hg or In (see Fig. 1 (b))¹².

B. Bi-In

For system's having signicant attractive interactions between unlike atoms, the surface structure is more complex. This is especially true of alloys such as Bi-In which from well-ordered intermetallic phases in the bulk solid. In Fig. 2 (b) we show the normalized rejective ity for the eutectic composition $B_{22}In_{78}$, measured at 80 C (4) along with the normalized rejectivity for liquid In at +170 C. The alloy exhibits a well dejected at 2.0 A which resembles the layering peak found for pure In (smudges). In addition, the rejectivity displays a modulation with a period of about 0.9 A This oscillation indicates that ordering over a short region at the surface occurs with a length scale nearly twice that of the longer-range layering. This suggests the presence of Bi-In pairs at the surface. A full report on the phase behavior of three different In-Bialloys will be given elsewhere.

C. Ga-Bi

The Ga-Bi system is an example of an alloy with repulsive heteroatomic interactions leading to a bulk miscibility gap. Below the monotectic temperature, $T_{m \, \text{ono}} = 222 \, \text{C}$, a

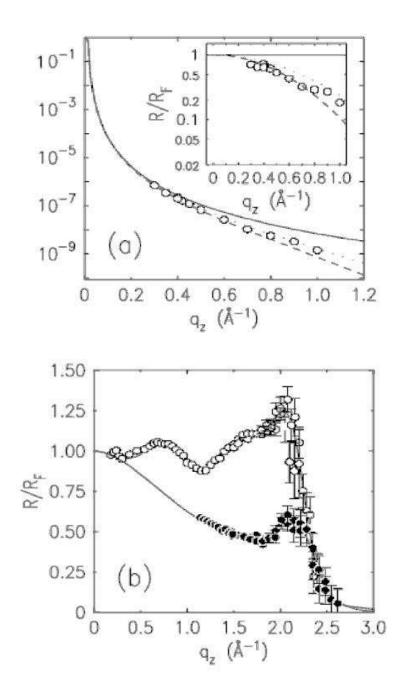

FIG. 2: (a) X-ray re ectivity from a K $_{80}$ N $_{a20}$ alloy measured by integrating over a large range of at xed + . The normalized re ectivity is shown in the inset. The dotted lines show a capillary wave roughness with no layering with = 12 and 15 A, respectively. (b) Normalized x-ray re ectivity of liquid In (+170 C, closed triangles) and In-22at % Bi (80 C, open triangles).

Ga-rich liquid coexists with a solid Biphase¹³. However, due to its lower surface energy a Bi m onolayer is expected to segregate at the surface of the Ga-rich liquid. Above $T_{m \text{ ono}}$, Ga-Bi exhibits a thick wetting lm, as predicted for all binary m ixtures with critical demixing⁴. This transition occurs at a characteristic wetting temperature T_w below the critical temperature T_{crit}^{13} . Above T_w , a macroscopically thick Birich phase is expected to completely wet the less dense Ga-rich phase in de ance of gravity. The Biconcentration in the Ga-rich phase increases with increasing temperature as long as the Ga-rich liquid coexists with the solid Biphase.

The norm alized x-ray re ectivity spectra, $R = R_F$, for Ga-Biat 35 C and 228 C are shown in Fig. 3 (a) versus q_z , along with the prole for pure Ga at room temperature. At 35 C the norm alized rejectivity has a broad maximum at q=1 A 1 . As suggested by Lei et al. 7, this is consistent with a density prole with a thin, high density monolayer of Bi.

We have the rectivity proles to simple density proles using Eq. (1). The tted rectivities are shown in Fig.3(a) (solid lines). At + 35 C the local density prole exhibits a top-layer density which is about 1.5 times higher than the Gabulk liquid density. The 3:4 0:2 A layer spacing between the surface and the adjacent Galayer obtained from the ts is much larger than the 2:5 0:1 A layer spacing obtained in liquid gallium. The data show that the surface layer has a higher density than in the underlying Ga-rich subphase, con ming the surface segregation of a Bimonolayer.

The behavior of the same alloy at 228 C is markedly dierent: a sharp peak in R (q) has emerged, centered around 0:13 A 1 (Fig. 3(a)). The peak at small q indicates the presence of a thick surface layer with a density greater than that of the bulk subphase. The absence of additional oscillations following the sharp peak suggests that the boundary between the two regions must either be diuse or rough. The persistence of the broad maximum at q_2 0:75A 1 indicates that B imonolayer segregation coexists with the new ly formed wetting lm. Fits to a simple two-box modelyield a lm thickness of 30A consistent with ellipsometry results 13 , and a surface density consistent with the high density liquid phase of the bulk alloy. The temperature dependent rectivity will be reported elsewhere 12 .

In Fig. 3(b) G ID data are shown from the same Ga-Bialloy in the temperature range from 150 to 255 C.D ata at 35 C was previously reported 10 . In the liquid Ga-rich phase the Biconcentration ranges from 3.3 at% to 17.8 at%. At each temperature data was taken above and below $_{\text{crit}} = 0.14$ at = 0.08 (symbols) and at = 0.30 (lines). At = 0.08

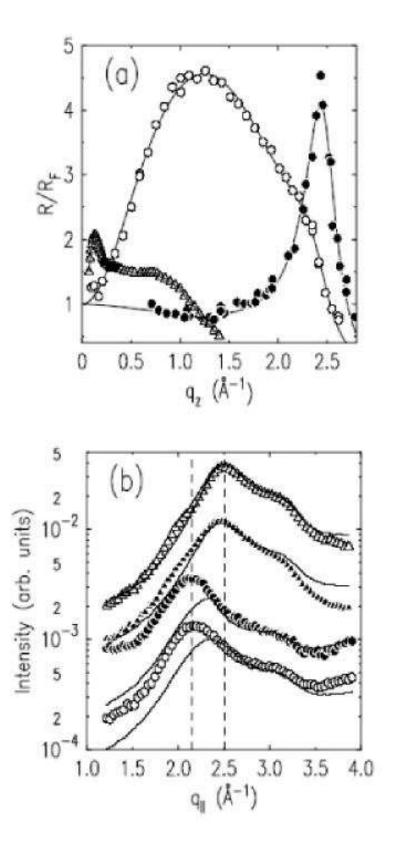

FIG. 3: (a) Normalized x-ray re ectivity of liquid Ga (+25 C,), and on the Ga-Bitwo-phase coexistence curve at 35 C () and 228 C. (b) Grazing incidence direction from Ga-Bi at 150 C (lled triangles), 205 C (4), 228 C, and 255 C () at = 0.08. The solid line shows corresponding pro less for = 0.30 where the bulk is pregion inately sampled. The data was acquired using Soller slits, $0.05 \, \text{A}^{-1}$ FW HM. Still, it was not possible to reliably subtract the background.

the x-ray penetration depth equals 28A or about 10 atom ic layers.

The solid lines in Fig. 3(b) at 150 C show the bulk liquid scattering which is predominately from pure G a since the Biconcentration is low. The broad peak at $q_k = 2.5 \, \text{A}^{-1}$ and the shoulder on the high-angle side of the peak are in agreement with the bulk liquid G a structure factor 15.

There is no evidence for a peak or shoulder at the position corresponding to the rst peak of the Biliquid structure factor at $q_k=2.2\,\mathrm{A}^{-1}$. This is expected since the surface regime is so much smaller than the bulk volume sampled. For $=0.08<_{\mathrm{c}}$, the x-rays penetrate to a depth of only about 30 A. Here a shoulder appears on the low-q side of the gallium liquid peak, due to enhanced sensitivity to the Bi surface monolayer. Between 150 C and 205 C () there is little change in the G ID data, except a slight increase in the shoulder associated with the Bim onolayer.

Above $T_{m \, ono}$ there is a dram atic change in the G ID pro les. In Fig.3(b), G ID data is shown at 228 C and 255 C. In both cases, for > c the peak has shifted to q_k 2:3 A 1 from the 2.5 A 1 peak position found at lower temperatures. This results from the much higher Bi concentration in the bulk at the higher temperatures and the larger atom ic size of Bi. Even more dramatic is the shift in the peak position for < crit where the peak is at 2.15 A 1 . Thus, the surface region contains considerably more Bi than the underlying bulk alloy. This inding is consistent with the wetting layer observed in the x-ray rejectivity measurements.
