W e present simulations of the interm ediate state of type-I superconducting lm s solving the time dependent G inzburg-Landau equations, which include the dem agnetizing eds via the B iot-Savart law. For sm all square samples we nd that, when slow ly increasing the applied m agnetic edd H_a, there is a saw-tooth behavior of the magnetization and very geometric patterns, due to the in uence of surface barriers; while when slow ly decreasing H_a, there is a positive m agnetization and sym m etry-breaking structures. W hen random initial conditions are considered, we obtain droplet and laberynthine striped patterns, depending on H_a.

PACS num bers: 74.25.-q,74.25 H a,75.60.-d

In 1937 Landau modeled the intermediate state (IS) in thin slabs of type-I superconductors, assuming a periodic structure of alternating stripes of norm al and superconducting phases.¹ D irect experim ental observation of the IS revealed that, while in som e cases its structure resembled the Landau picture, very complex patterns and history dependence were usually seen.^{2,3,4,5} Sim ilar type of complex structures were later observed in twodim ensional (2D) system s where there is a competition am ong interfacial tension and long-range interactions⁶ like thin magnetic lms, ferrom agnetic uids, Langmuir and lipid m onoloyers, and self-assem bled atom s on solid surfaces.⁶ Labyrinthine patterns, and a transition from structures of droplets to stripes are typically observed. The rich physics found in these 2D systems has motivated a renewed interest in the study of the IS in type-I superconductors in several recent experim ents.^{7,8,9,10,11}

M ost of the theoretical progress^{12,13,14,15,16,17,18,19,20} has been m ade by modeling the IS with periodic arrays of norm al and superconducting phases. Recently, a current-bop m odel¹⁸ which allows to describe simple non periodic patterns has been introduced, but a fully consistent theoretical description¹⁹ of the experimental patterns is still needed. Another important problem not addressed neither experimentally nor theoretically in type-I superconductors is the study of the IS in samples of sizes comparable with the expected periodicity of the patterns, while interesting m esoscopic" behaviors have been found in type-II superconductors with sizes of the order of few times the magnetic size () of vortices.²¹

In this paper we report detailed simulations of sm all square type-I superconductors by solving the time dependent G inzburg-Landau (TDGL) equations for slabs of thickness d. We consider the \non-branching case", where d d_s 800 ()¹³, which can be well approximated by reducing the equations to a 2D problem, as done for example in Ref.12,18. We therefore assume that the current density J and the order parameter can be replaced by their average over z for d=2 < z < d=2, i.e. J(R;z) ! J(R) and (R;z) ! (R), with R = (x;y) the in-plane coordinate. The TDGL equations,^{17,18} in

the gauge where the electrostatic potential is zero, are

$$\frac{\varrho}{\varrho t} = \frac{1}{G} j j^{2} \qquad 1 \qquad \frac{2}{G} r \qquad \frac{2e}{rC} A \qquad (1)$$

$$J = \frac{1}{8 e^{-2}} Im \qquad r \qquad \frac{2e}{rC} A \qquad \frac{n}{c} \frac{\varrho A}{\varrho t} (2)$$

Here r, A, J are 2D in-plane vectors, $_{\rm G} = {}^{2}$ =D, D is the di usion constant, $_{\rm n}$ the normal state conductivity, (T) the penetration depth and (T) the coherence length. These 2D approximated TDGL equations couple with the perpendicular component of B. Following Ref22 we express the z-averaged sheet current J by a scalar function g: J(R) = r 2g(R). This guarantees that r J = 0, the physical meaning of g(R) being the local magnetization or density of tiny current loops. Next one relates g(R) with B_z(r) = r A j at z = 0 and the applied eld H_a by means of the Biot-Savart law $\frac{22}{2}$

$$B_{z}(R;z=0) = H_{a} + \frac{1}{c}^{Z} Q(R;R^{0})g(R^{0})d^{2}R^{0}$$
(3)

The kernel Q satis es Q (R_{R1} ; R_2) 0 (R₂ R1); $d=R^3$; and $d^2RQ(R) = 0$ (due to d) = Q(R ux conservation). To a good approximation the kernel can be given by (see K.Maki in Ref. 12): O (R) = $d=[\Re^{2} + d^{2}=4]^{3=2}$. The boundary conditions 4 (R) $\frac{2e}{2}A$) $\frac{1}{2} = 0$ and $g_{j_b} = 0$. We solve the are (r equations with a nite di erence scheme with discretization x = y = 0.5 (0), using link variables to maintain the gauge invariance.¹⁷ W e norm alize time by $t_0 =$ $4 n^2 = c^2$, A by H_{c2} (0) (0), T (tem perature) by T_c , and take $_{G} = t_{0} = 12$. To obtain g(R) we invert (3) using the conjugate gradient m ethod as done in R ef.23.

We show results for square samples of size L L with L = 256 (0), thickness d = 40 (0); = = = 0.6; T = $0.8T_c$ and time step t = 0.25 (we also obtained sim - ilar results for L = 120 (0) 256 (0), d = 10 (0) 40 (0) and = 0.4 0.6). We performed simulations of the intermediate state following three di erent procedures: (i) slow ly increasing the magnetic eld from H_a = 0, (ii) slow ly decreasing the magnetic eld from the norm al state (H_a > H_c) and (iii) starting from random initial

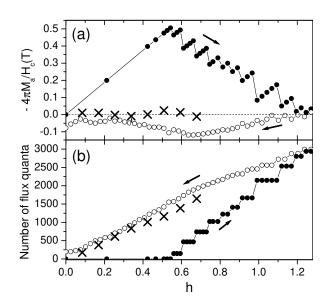

FIG.1: (a) (B H_a)=H_c(T) and (b) the number of ux quanta obtained increasing (closed circles), decreasing (open circles) the external magnetic eld h = H_a=H_c(T), and with random initial conditions (crosses).

conditions for each value of H_a. The global results for the three cases are summarized in Fig.1. We show the apparent magnetization, 4 M_a = hB_zi H_a (realmagnetization is 4 M = B H, but M_a is what can be determ ined experimentally), in Fig.1 (a), and the number of ux quanta inside the sample, N $_{\circ} = (A + \frac{J_{a}}{j f})dl$, in Fig.1 (b), as a function of h = H_a=H_c(T).

(i) Slowly increasing the magnetic eld. We start from $H_a = 0$ with a state with j (R) j² = 1 and B (R) = 0 and increase H_a in small steps, after reaching a stationary state for each eld (when $j = E j < 10^6$; where E is the change in energy between consecutive time steps). W e observe a M eissner state for H $_a$ < H $_p$ = 0.56H $_c$. Surface barriers preclude the penetration of ux below H $_{p}$. The surface barrier in m acroscopic type-I superconductors can lead to relatively large rst penetration elds H p, which depend on the sample shape and dimensions.^{7,15} Here the smallness of our system strongly enhances this e ect. W e observe that at H & H p four long chunks of the norm alphase, carrying hundreds of ux quanta, enter from each side of the square and equilibrate in the pattern shown in Fig.2(a). At a higher eld $H_{p;2}$, som e other four chunks of ux enter and form the pattern seen in Fig2(b). Further increasing the eld, more complex structures form, as shown in Fig.2 (c) and (d). The normaldomains tend to stay in the centre of the sample, leaving a ux-free zone near the edge. Above H_c, ux has fully entered inside the system and there is only surface superconductivity until $H_{c3} > H_{c}$. The internal structure of the dom ains is detailed in Figs2 (e) and 2(f) which show transversal cuts of j (R) j 2 and B $_z$ (R) taken at the center of one of the faces for h = 0.58. In Fig. 2(e) we see that in the norm al regions there is a

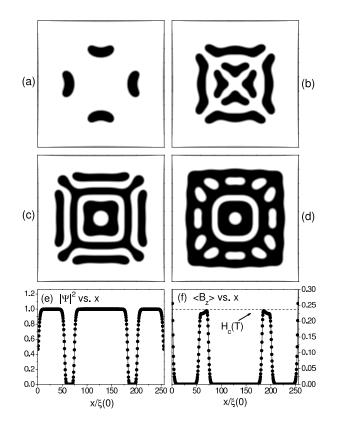

FIG.2: (a)-(d) Spatial patterns of j (r) j^2 obtained continuously increasing $h = H_a = H_c$ from h = 0. (a) h = 0.58, (b) h = 0.65, (c) h = 0.72 and (d) h = 0.78. G ray scale ranging from black for j (r) $j^2 = 0$ to white for j (r) $j^2 = 1$. (e) and (f) show transversal cuts of j (r) j^2 and hB_z i taken at the center of one of the faces for h = 0.58 (Fig. 2 (a)). P aram eters: = 0.6, d = 40 (0) and sam ple size 256 (0) 256 (0).

sharp drop to zero of j j² and that B $_z$ H_c(T) (see Fig.2(f). The global structure of the patterns of the IS observed in Figs 2 (a)-(d) follow the geometry of the sam ple and have the symmetry of the square. In general, we nd that the entrance of the norm alphase occurs only for discrete values of penetration elds H p;i where several ux quanta are nucleated at the four sides of the square, while for $H_{p;i} < H_a < H_{p;i+1}$, there is no ux entrance. This shows up as a saw-tooth behavior in the m agnetization in Fig.1 (a) and as a series of plateaus and jum ps in the num ber of ux quanta vs. H_a in Fig.1(b). This type of behavior is sim ilar to the results observed in mesoscopic type-II system s²¹ which also show a saw tooth behavior of the magnetization. However, while in Ref. 21 each jump in M_a corresponds to the entrance of one quantum of ux (one vortex), here at each jump in M_a several hundreds of ux quanta have entered. Our results suggest the existence of a \m esoscopic-like" behavior in sm all type-I sam ples. This novel behavior appears when the linear size L of the sample only allows for a sm all num ber of norm ald om ains inside the system . This means that L is not more than one order of magnitude

larger than the periodicity of the patterns at interm ediate elds. Indeed, we have found sim ilar m = 0.01 behavior for sizes in the range L 256 (0).

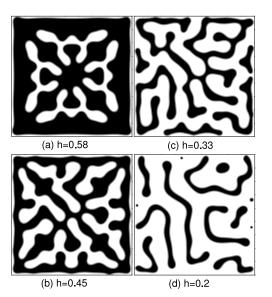

FIG.3: Spatial patterns of j (r) j^2 obtained decreasing h from the norm al state at h 1. Same parameters as in Fig.2.

(ii) Slowly decreasing the magnetic eld. We start from $H_a > H_c$ with a state with = 0 and B = H_a and decrease H_a in sm all steps, after reaching a stationary state for each eld. The resulting intermediate state patterns are shown in Fig.3. When H_a H_c the superconducting phase enters into the sample and the total number of ux quanta is reduced. At rst, the superconducting phase forms four chunks embedded within the normal phase, which nearly follow the square symmetry of the system, as shown in Fig.3(a). However, we observe that when decreasing the eld the square symmetry is always broken in the patterns. The breaking of symmetry is stronger the further we decrease the eld. In this way, labyrinthine patterns are form ed at mid-range elds, as can be seen in Figs.3 (b) and (c). In general, the expulsion of ux occurs gradually when decreasing H_a as shown in Fig.1(b). For low elds we see that thin stripes of norm alphase are trapped within the sample, as shown in Fig.3 (d). The di culty for expelling ux is due to the surface barrier and results in a positive magnetization as a function of h as shown in Fig.1 (a). Even at h = 0, a small amount of ux remain trapped in the sample, as evidenced in Fig.1 (b), where the num ber of ux quanta is nite at h = 0, and in Fig.1 (a), where $M_a > 0$ at h = 0. In experiments in macroscopic samples it has been observed that som e trapped ux remains in the system at h = 0 when decreasing the eld³ and in some Sn lm s a positive magnetization has been obtained when decreasing H_a.⁵ It is interesting to mention that a similar positive magnetization was observed in mesoscopic type-II superconductors²¹ when decreasing H_a, and attributed to the importance of surface barriers.

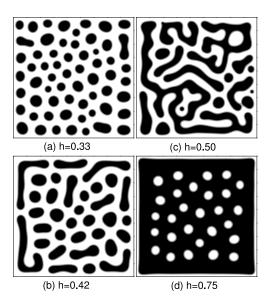

FIG.4: $j(r)j^2$ patterns obtained using random initial conditions. Same parameters as in Fig2.

(iii) Random initial conditions. The structures of the IS discussed above, obtained either increasing or decreasing the magnetic eld, are strongly in uenced by the surface barriers and/or the geometry of the small sample simulated. In a lm of large linear size L the dem agnetization factor N is such that 1 N / d=L 0, and therefore we expect that B H_a. To obtain stationary states m ore typical of the bulk behavior of large sam ples, we start with a initial condition with random values of A and , such that we satisfy $hBi = H_a$ from the start, and that the initial state is superconducting in average, hj j²i > 0. W e perform ed simulations with this initial condition for di erent values of h, and let the system to evolve for each case, using a stronger criterion for assum ing stationarity: $j = E j < 10^9$. We obtain that in the stationary state most of the ux remains inside the sample and $hB_z i$ H_a 0 as can be seen in Fig.1(a). The structures obtained are shown in Fig. 4. For low elds, we observe in Fig.4 (a) that the interm ediate state consists of alm ost circular droplets of the norm alphase. For higher elds, the droplets start to coalesce into long lam ellar-like dom ains, as seen in Fig.4 (b). At interm ediate elds, as shown in Figs.4 (c), labyrinthine patterns of stripes of the norm alphase are form ed. For high elds close to H_c we observe almost circular droplets of the superconducting phase embedded within the mostly norm alphase, see Fig.4 (d). Sim ilar type of structures, with droplets of one or the other phase at low and high elds, and with labyrinthine patterns of stripes at mid range elds has been observed experimentally for example in Figs 2.8 (a)-(f) of Ref 2 for a lead thin lm. An important feature we nd in our small system is that there is a thin layer of superconducting phase at the surface (see Fig. 4), which allows for the screening M eissner currents.

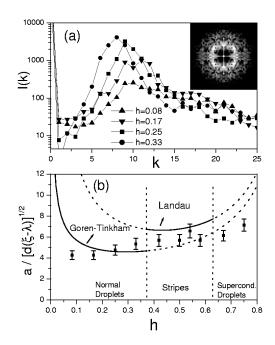

FIG. 5: (a) Spectral intensities obtained from $j(r)j^2$ at di erent magnetic elds, a maximum at k_0 is observed. The inset show sthe Fourier transform of Fig. 4(a). (b) Periodicity $a = 2 = k_0$ of each structure as a function of h. The lines correspond to the Landau and the G oren-T inkham models.

We analyze the structures obtained in Fig.4, by calculating the spectral transform of the superconducting order parameter, I (k) = $\frac{R}{drj}$ (r) $j^2 \exp(ik r)^2$, which is shown in Fig.5 (a). The non-periodicity and complex

structure of the patterns results in very broad maxim a in I(k) at nite wave vectors $k_0 = 2 = a$ which de ne a typical length scale a. In the case of low and large elds, a would correspond to the typical distance between droplets, while for mid-range elds, a would correspond to the average widths of the stripes in the labyrinthine patterns. We plot a in Fig.5 (b) and compare it with the Landau model of stripes¹ and with a model of Goren and Tinkham for a periodic array of droplets or \setminus ux spots".¹⁴ W e see that the Landau m odel agrees qualitatively with the results obtained at mid-range h (for these elds the patterns of Fig.4 can have a mixture of \stripes" with a few droplets, which make a smaller than the Landau value). On the other hand, at low h the Goren-Tinkham model does not agree well with the size of the droplets obtained. A lso in some experiments4,10 it has been found a departure from the Goren-Tinkham modelat low elds.

In conclusion, our simulations predict that the strong in uence of the surface barriers in small type-I samples will lead to a saw-tooth behavior of the magnetization and very geometric patterns when slow ly increasing H_a, and to a positive magnetization and symmetry-breaking structures when slow ly decreasing H_a. These results suggest the existence of a \mesoscopic-like" behavior in the IS when the sample linear size is of the order of a few times the periodicity of the patterns. It will be interesting if experiments on small samples of type-I superconductors could be performed.
