## Abstract

The electron spin-lattice relaxation (SLR) times  $T_1$  of Yb<sup>3+</sup> ions were measured from the temperature dependence of electron spin resonance line width in Y<sub>0.99</sub>Yb<sub>0.01</sub>Ba<sub>2</sub>Cu<sub>3</sub>O<sub>x</sub> with different oxygen contents. Raman relaxation processes dominate the electron SLR. Derived from the temperature dependence of the SLR rate, the Debye temperature ( $\Theta_D$ ) increases with the critical temperature  $T_c$  and oxygen content x. This relationship between  $T_c$  and  $\Theta_D$  can be well understood in terms of the modified Bardeen–Cooper–Schriefer theory of phonon mechanism for a strong electron–phonon coupling.

# 1. Introduction

The Debye characteristic temperature  $\Theta_D$  is a quintessential quantity characterizing phononrelated properties of a solid state. This parameter is especially important for the high-temperature superconducting (HTSC) compounds, because the relationship between  $\Theta_D$  and the critical temperature ( $T_c$ ) may be very useful for the determination of the possible mechanism of HTSC. As a rule, the value of  $\Theta_D$  is extracted either from elastic constant or specific heat measurements. The experimental data, which were obtained for  $\Theta_D$  in YBa<sub>2</sub>Cu<sub>3</sub>O<sub>x</sub> (YBCO) compounds using these methods, are very controversial. So, the value of  $\Theta_D$  measured from ultrasonic sound velocities in the work of Ledbetter [1] is much lower than that derived from the specific heat studies [2]. Moreover, as was shown in Ref. [3],  $\Theta_D$ in YBCO depends strongly on temperature, and this dependence is usually not observed in other compounds [4]. Therefore, it is very reasonable to estimate value of  $\Theta_D$  by other methods.

Here, we present data of  $\Theta_D$  obtained from the electron spin–lattice relaxation (SLR) measurements of doped rare-earth Yb<sup>3+</sup> ions in YBCO

ceramic samples with different oxygen contents, x, and therefore, with different critical temperatures,  $T_{\rm c}$ .

#### 2. Experimental details

The polycrystalline powder  $YBa_2Cu_3O_x$  (x = 6.0, 6.45, 6.67 and 6.85) samples were prepared by the standard solid-state reaction technique. Appropriate proportions of Y2O3, BaCO3, CuO were dried at 400-500°C, mixed and ground thoroughly into a fine powder. The doped Yb<sup>3+</sup> were added using an oxide Yb<sub>2</sub>O<sub>3</sub> in a ratio Yb:Y = 1:100. The powder were treated then in a two stage heating process. First, samples with a high oxygen content ( $x \simeq 7$ ) were obtained. These HTSC ceramics were annealed to reduce x, which depends strongly on annealing temperature. The oxygen content was defined from the lattice parameter along the crystallographic *c*-axis [5] using X-ray diffraction. The values of  $T_c$  for different x (Table 1) were determined from the temperature dependence of microwave absorption in a low magnetic field.

It is very important to investigate a single crystal samples of YBCO, because of their strong anisotropy. In the present work, the YBCO powders were milled (size =  $1-3 \mu m$ ), then mixed with paraffin or epoxy resin and placed in a glass tube in a strong magnetic field ( $\ge 15 \text{ kG}$ ) to prepare a quasi-single-crystal samples (or crystallites). The *c*-axes of these crystallites were predominantly oriented along the direction *C* of the external magnetic field *H* after hardening of epoxy resin. ESR

Table 1

Critical and Debye temperatures, the minimal ESR line width  $\Delta H_{pp}^{min}$ , effective g-values and the SLR parameter C against oxygen content  $x^a$ 

x	6.85	6.67	6.45	6.0
$T_{\rm c}$ (K)	85	65	40	_
$\Theta_{\rm D}$ (K)	450	370	280	250
$\Delta H_{\rm pp}^{\rm min}$ (G)	95 (55 K)	90 (45 K)	75 (25 K)	95 (20 K)
g	3.0	3.1	3.15	3.45
$C (\times 10^{-7})$	1.06	4.23	15.3	50

<sup>a</sup> The values of  $\Delta H_{pp}^{min}$  were measured at temperatures, which are given in brackets. The g-values were estimated at  $T \simeq 50$  K with an accuracy of ~20%.

spectra were recorded on X-band (~9.25 GHz) IRES-1003 and THN-251 ESR spectrometers in the temperature range from 4 to 120 K.

#### 3. Results and discussion

Fig. 1 shows the complicated temperature dependence of the Yb<sup>3+</sup>–ESR peak-to-peak line width  $\Delta H_{pp}$  in YBa<sub>2</sub>Cu<sub>3</sub>O<sub>6.85</sub> for  $H \parallel C$  with a minimum at the temperature  $T_{min}$  and a small step of  $\Delta H_{pp}$  near  $T_c$ . The ESR measurements on this sample were discussed previously at  $T < T_{min}$  [6], and in this paper, we report on results above  $T_{min}$  only without discussion of the anomaly of  $\Delta H_{pp}$  near  $T_c$ .

We have observed a rapid increase of  $\Delta H_{\rm pp}$ , as *T* increases, in all investigated samples for  $T > T_{\rm min}$ . The dependence of this kind, which is very common for Yb<sup>3+</sup> ions in single crystals, is caused by a SLR only [7]. We have analyzed the character of the temperature dependence of the SLR rate  $T_1^{-1}$  to distinguish the dominating SLR process. Then, the similar approach as explained in Ref. [8] was applied to evaluate the ESR line width caused by SLR only ( $\Delta H_{\rm pp}^{\rm SLR}$ ) from the relation:

Fig. 1. Temperature dependence of the peak-to-peak ESR line width of  $Yb^{3+}$  ions in  $YBa_2Cu_3O_{6.85}$ , H||C.

$$(\Delta H_{\rm pp})^2 = \Delta H_{\rm pp}^{\rm SLR} \, \Delta H_{\rm pp} + (\Delta H_{\rm pp}^{\rm min})^2, \tag{1}$$

where  $\Delta H_{pp}^{\min}$  is the minimal ESR peak-to-peak line width. The values of  $\Delta H_{pp}^{\min}$  are given in Table 1 for all investigated samples. The formula (1) is given in another denotations in Ref. [9] and determines an observed line width by the superposition of ESR signals with a Gaussian and Lorentzian line shapes together. We have to take this fact into account in our case, because the ESR line has a Gaussian line shape at  $T = T_{\min}$  and arises due to inhomogeneities of the crystal electric field (CEF) potential, and the Lorentzian line shape is connected usually to the term  $\Delta H_{pp}^{SLR}$ .

nected usually to the term  $\Delta H_{pp}^{SLR}$ . The SLR rate  $T_1^{-1}$  can be expressed from  $\Delta H_{pp}^{SLR}$  as follows [10]:

$$T_1^{-1}(s^{-1}) = (\sqrt{3}/2)g\beta\hbar^{-1}\Delta H_{\rm pp}^{\rm SLR}(G)$$
  

$$\equiv 7.62 \times 10^6 g\,\Delta H_{\rm pp}^{\rm SLR}(G), \qquad (2)$$

where  $\beta$  is Bohr's magneton,  $\hbar$ , the Planck constant, and the *g*-factor  $g = g_{\parallel}$ . The values of  $\Delta H_{pp}^{min}$ and *g*, which depend very weakly on temperature, were measured in the temperature range from 25 to 55 K and are given in Table 1. The temperature dependences of the SLR rate  $T_1^{-1}$  for the samples with two different oxygen contents x = 6.85 and 6.0 are shown in Figs. 2 and 3, respectively. Thus, the Yb<sup>3+</sup>-relaxation rate reads  $T_1^{-1} \sim T^n$  (n = 5 for x = 6.85, n = 4 for x = 6.67, n = 3 for x = 6.45and 6.0). The dependence of such a kind corresponds to the Raman SLR process within the socalled "intermediate" temperature range, if both relations  $T \ll \Theta_D$  (then  $T_1^{-1} \sim T^9$ ) and  $T \ge \Theta_D$ ( $T_1^{-1} \sim T^2$ ) do not take place.

The relaxation rate  $T_1^{-1}$  of the Raman SLR process can be written in a common case as follows [7]:

$$T_1^{-1} = CT^9 f(\Theta_{\rm D}/T),$$
 (3)

where prefactor *C* will be discussed later, and the integral function  $f(\Theta_D/T) \equiv f(z) \equiv I_8(z)/I_8(\infty)$ . The calculated values of the integral  $I_8(z) = \int_0^z x^8 e^x/(e^x - 1)^2 dx$  are given [11]. Our experimental data on SLR rate in YBCO can be described quite well using the values of prefactor *C* and  $\Theta_D$  from Table 1.

Fig. 2. Temperature dependence of the SLR rate of Yb<sup>3+</sup> ions in YBa<sub>2</sub>Cu<sub>3</sub>O<sub>6.85</sub> measured from the ESR line width ( $\blacksquare$ ); empty circles show data of the <sup>170</sup>Yb<sup>3+</sup> Mössbauer spectroscopy studies performed by Hodges et al. [13] in Y<sub>0.97</sub>Yb<sub>0.03</sub>Ba<sub>2</sub>Cu<sub>3</sub>O<sub>7</sub>. Dotted line represents the best fit according to Eq. (3) with  $C = 1.06 \times 10^{-7}$  and  $\Theta_{\rm D} = 450$  K. Solid line corresponds to the  $T_1^{-1} \sim T^5$  dependence.

Fig. 3. Temperature dependence of the SLR rate of Yb<sup>3+</sup> ions in YBa<sub>2</sub>Cu<sub>3</sub>O<sub>6.0</sub>. The solid curve is the fit to the Eq. (3) with  $C = 50 \times 10^{-7}$  and  $\Theta_{\rm D} = 250$  K.

Although the accuracy of determination of  $\Theta_{\rm D}$  was of about  $\pm 10\%$ , the estimated value of  $\Theta_{\rm D} = 450$  K for x = 6.85 corresponds very well to the literature data [2,3]. The comparison for the samples with x = 6.67; 6.45 is not so satisfactory, however, it supports the main conclusion of Refs. [1,12] that  $T_{\rm c}$  is increasing approximately linearly with increase of  $\Theta_{\rm D}$ .

In Fig. 2, we show also the temperature dependence of the SLR rate of ytterbium ions extracted from the <sup>170</sup>Yb<sup>3+</sup> Mössbauer spectra in a YBa<sub>2</sub>Cu<sub>3</sub>O<sub>x</sub> specimen with  $x \approx 7.0$  [13]. A very good correlation to our SLR results seems to confirm that the temperature dependence of the ESR line width at  $T > T_{min}$  is caused mainly by the SLR of the Yb<sup>3+</sup>-ions.

The performed studies of the SLR have revealed that by decreasing of oxygen content x and reduction of  $T_c$ ,  $\Theta_D$  decreases and the prefactor C on  $T^9$  increases. We can evaluate  $\Theta_D$  using the well-known expression [4]:

$$\Theta_{\rm D} = \frac{\hbar}{k} \left( \frac{6\pi^2 q N \rho}{M} \right)^{1/3} v_{\rm m},\tag{4}$$

where  $v_{\rm m}$  is the mean sound velocity,  $\rho$ , the density of material, and M, the molecular weight, q, the number of atoms in the molecule, and N, the Avogadro number. The parameter C can be obtained for the Kramer ions from the relationship [14]:

$$C = \frac{9!\hbar^2}{\pi^3 \rho^2 v_{\rm m}^{10}} \left(\frac{k}{\hbar}\right)^9 \times \frac{\sum_{nm} |\langle a|V_n^m|c\rangle|^2 \sum_{nm} |\langle c|V_n^m|b\rangle|^2}{\Delta^4}$$
(5)

where  $\Delta$  is the CEF splitting between the ground and first excited states. The value after sign  $\times$  is usually approximately equal 1.

Therefore, from relations (4) and (5), it is clear that  $\Theta_D$  and *C* are connected in some way to the sound velocity *v*, and by increasing of  $\Theta_D$ , *C* decreases drastically (as  $v^{-10}$ ). This coincides quite well with our experimental data of  $\Theta_D$  and *C* in the samples with x = 6.85 and 6.45 (Table 1). Thus,  $\Theta_D$  for x = 6.45 is of about 1.5 times smaller than one for x = 6.87, and the corresponding prefactor C decreases in 15 times in a good accordance with the Eqs. (4) and (5).

Taking into account the formula (4) for YBa<sub>2</sub>Cu<sub>3</sub>O<sub>7</sub> ( $\rho = 5.78$  g/cm<sup>3</sup>, q = 13), we have

$$\Theta_{\rm D}(K) = 1.25 \times 10^{-3} v_{\rm m} \ ({\rm cm/s}).$$
 (6)

As was shown in Ref. [1], we can find  $v_{\rm m} = 2.89 \times 10^5$  cm/s and  $\Theta_{\rm D} = 362$  K from the expression for mean sound velocity.

$$3v_{\rm m}^{-3} = v_{\rm l}^{-3} + 2v_{\rm t}^{-3}, \tag{7}$$

using the literature data of the YBCO sample with  $T_c = 86$  K for the longitudinal and transversal sound velocities ( $v_1 = 4.25 \times 10^5$  cm/s and  $v_t = 2.62 \times 10^5$  cm/s, respectively). Accordingly, we can estimate the value of  $C \approx 1.144 \times 10^{-6}$ , which correlates well with data of our SLR measurements.

However, the excellent agreement with our SLR experimental results is observed, if we take  $v_{\rm m} = 3.6 \times 10^5$  cm/s. Both calculated values of  $\Theta_{\rm D} = 450$  K and  $C \simeq 1.27 \times 10^{-7}$  correspond then accurately to the data of SLR studies.

Finally, a possible mechanism of high-temperature superconductivity can be deduced from the functional dependence of  $T_c$  on  $\Theta_D$ . Thus, Ledbetter [1,12] has applied the usual BCS expression of  $T_c$ :

$$T_{\rm c} = 0.86\Theta_{\rm D} \exp(-\lambda^{-1}), \qquad (8)$$

where an electron–phonon coupling constant  $\lambda$  is given by

$$\lambda = C' M \langle \omega^2 \rangle, \tag{9}$$

and has concluded that  $\langle \omega^2 \rangle \sim (\Theta_D)^2$  and the BCS formula cannot describe the experimental data [12], where  $T_c$  increases with the increase of  $\Theta_D$ . In fact, combining Eqs. (8) and (9), one can derive that  $T_c$  decreases with increase of  $\Theta_D$  for a weak electron-phonon coupling ( $\lambda < 1$ ), and  $T_c \approx \Theta_D$  in a strong coupling limit  $\lambda > 1$ . However, both these relations contradict to our and other experiments in YBCO.

The modification of the BCS theory led to the extended McMillan's equation for various classes of strong-coupled superconductors, which is used

extensively for a phonon mechanism of HTSC [15]:

$$T_{\rm c} = \frac{\Theta_{\rm D}}{1.45} \exp\left(-\frac{1.04(1+\lambda)}{\lambda - \mu^*(1+0.62\lambda)}\right),\tag{10}$$

where  $\mu^*$  is parameter of effective Coulomb repulsion. For  $\lambda < 1$  and  $\mu^* < \lambda$  ( in a weak-coupling limit), Eq. (10) transforms into Eq. (8). The parameters  $\lambda$  and  $\mu^*$  can be defined for a better description of our measurements for a strong-coupled systems. The corresponding calculations with the formula (10) for  $\lambda \leq 10$  result in that  $T_c \approx 74.7$  K (for  $\Theta_D = 450$  K,  $\lambda \approx 4$ ),  $T_c \approx 68.0$  K( $\Theta_D = 370$  K), and  $T_c \approx 56.3$  K ( $\Theta_D = 280$  K,  $\lambda \approx 10$ ), if  $\lambda = 8 \times 10^5/\Theta_D^2$  and  $\mu^* = 0.1$ .

In summary, we have presented an alternative possibility to determine Debye temperature in  $YBa_2Cu_3O_x$  by means of the electron SLR of doped  $Yb^{3+}$ -ions, if Raman processes are dominant in SLR. The relationship between critical and Debye temperatures, derived from these studies for different oxygen contents, can be good explained using McMillan's equation in a strong-coupling limit.
