Abstract

We nd Marginal Ferm iLiquid (MFL) like behavior in the Hubbard model on a square lattice for a range of hole doping and on-site interaction parameter U. Thereby we use a self-consistent projection operator method. It enables us to compute the momentum and frequency dependence of the single-particle excitations with high resolution. The Ferm i surface is found to be hole-like in the underdoped and electron-like in the overdoped regime. When a comparison is possible we indiconsistency with nite temperature quantum M onte Carlo results. We also india discontinuous change with doping concentration from a MFL to Ferm i liquid behavior resulting from a collapse of the lower Hubbard band. This renders Luttinger's theorem inapplicable in the underdoped regime.

PACS: 71.10.-w, 79.60 Bm, 71.18.+y, 74.72.-h

A fier the discovery of high-tem perature superconductivity in layered Cu based perovskites it was found that those materials exhibit quite unusual properties in the normal state. For example, in underdoped materials, i.e., for hole concentrations less than the one leading to the highest superconducting transition temperature, the temperature dependent resistivity is found to be (T) T in the normal state. A leo the nuclear relaxation rate, e.g., of Y Ba₂Cu₃O₇ has an unusual temperature independent contribution.

A in ing for an explanation of these strong deviations from a norm alm etalbehavior Varma et al.¹ developed the M arginal Ferm i Liquid (M FL) theory. This theory assumes that the frequency ! and temperature T dependent self-energy (!;T) of the electrons behaves for ! > T like Re (!;T) ! lnj! j and Im (!;T) j! j in contrast to ordinary Ferm i liquid theory where Re (!;T) ! and Im (!;T) ! ² holds. Note that at zero temperature the M FL form of the self-energy in plies a diverging elective m ass at the Ferm i energy. W ith these assumptions most of the observed strong deviations from norm alm etal behavior could be explained surprisingly well. However, the m icroscopic origin of M FL behavior of the self-energy has remained an open problem.

There have been detailed studies of the two-dimensional (2D) Hubbard model as a sim – ple model for the high-T_c cuprates² mainly by using advanced numerical techniques. We mention in particular the Lanczos method², the Quantum Monte-Carlo (QMC)^{3{5} method or calculations based on the Dynamical Cluster Approximation (DCA)⁶.

A perturbation analysis of the half-lled case at T = 0 has shown that in the weak C oulom b interaction limit a MFL type of self-energy is obtained⁷. It is due to the van H ove singularities which one is dealing with in this particular case. But we know that electron correlations are strong in the superconducting cuprates and that at T = 0 the system is an antiferrom agnet²^{;5;8}. It is also known that by hole doping the antiferrom agnetic correlations are rapidly suppressed²^{;5;6;9}. Nevertheless MFL behavior continues to exist in the underdoped regime and the question is whether or not it can be explained within the 2D H ubbard m odel with fairly strong interactions.

The aim of this letter is to demonstrate that MFL behavior can indeed be derived from a doped 2D Hubbard model on a square lattice at T = 0 and large on-site interaction. This has become possible with the help of a recently developed self-consistent projection operator method (SCPM)¹⁰. It allows for high resolution calculations of the self-energy as regards its momentum and energy and avoids certain problems previous numerical calculations have had to face.

The SCPM is an extension to the nonlocal case of a projection operator coherent potential approximation¹¹. The latter was shown to be equivalent to the many-body CPA, the dynamical CPA as well as the dynamical mean-eld theory¹². In the following we outline brie y the main equations which are used before we present the numerical results demonstrating MFL behavior. More detailed derivations of the equations are found in the original literature^{10{12}.

Starting point is the retarded G reen function

$$G_{k}(z) = \frac{1}{z_{k}(z)}$$
 (1)

Here z = ! + i where is a positive in nitesimal number, k is the Hartree-Fock oneelectron dispersion measured from the Ferm ienergy and k (z) is the self-energy calculated from the nonlocal memory matrix M_{ij} according to

$$_{k}(z) = U_{j}^{2} M_{j0}(z) \exp(ik R_{j})$$
 (2)

W hile U denotes the Hubbard on-site interaction, R_j is the position vector of site j. We calculate M_{ij}(z) by using an incremental cluster expansion up to two-sites contributions

$$M_{ii}(z) = M_{ii}^{(i)}(z) + M_{ii}^{(il)}(z) M_{ii}^{(il)}(z)$$
(3)

$$M_{i \neq j}(z) = M_{i \neq j}^{(ij)}(z) ; \qquad (4)$$

where $M_{ii}^{(i)}(z)$ and $M_{i\in j}^{(ij)}(z)$ are matrix elements of the cluster memory matrices $M_{lm}^{(c)}(z)$ (c = i;ij). The latter can be expressed in terms of a "screened memory matrix" $\hat{M}^{(c)}(z)$ and a matrix $L^{(c)}(z)$ which describes on-site excitations. It is

$$M_{lm}^{(c)}(z) = \dot{M}^{(c)} 1 L^{(c)} \dot{M}^{(c)}^{1}$$

$$\lim_{lm}$$
(5)

The matrices have dimensions 1 1 when c = i and 2 2 when c = (ij). Speci cally $L^{(i)}(z) = U(1 2hn_i i) = [nn_i i(1 hn_i i)] while <math>L^{(ij)}(z)$ is a diagonal matrix with elements $L^{(i)}(z)$ and $L^{(j)}(z)$. A susual hn_i i is the average electron number at site i with spin . The screened memory matrix is calculated from renormalized perturbation theory¹⁴ as

$$\hat{M}_{ij}^{(c)}(z) = A_{ij}^{Z} \frac{d \ d^{0} d^{0} \alpha_{ij}^{(c)}(z)}{z^{0} + \omega} (z)^{(c)} (z)^{($$

with $A_{ii} = [m_i \ i(1 \ m_i \ i)] = [m_i \ i_c(1 \ m_i \ i_c)]$ and $A_{i \neq j} = 1$. Here $m_i \ i_c = {}^{R} d_{1i}^{(c)}()f()$ with f() denoting Ferm i's distribution. The matrix ${}^{(c)}_{ij}()$ describes the density of states of a system with an empty site i (or sites i and j) embedded in a medium with a coherent potential $^{(c)}(z)$. This coherent potential is determined self-consistently from $^{(c)}(z) = N {}^{1}{}^{P}_{k}_{k}(z)$ where N is the number of sites. Moreover, $(;{}^{0};{}^{0}) = f()f({}^{0})f({}^{0}) + f()f({}^{0})f({}^{0})$. We want to emphasize that in Eqs. (2)-(4) allmemory matrices with site i separated su ciently far from site j are taken into account until convergency is obtained.

It follows from Eqs. (5) and (6) that the self-energy reduces in the lim t of small U to second order perturbation theory while in the lim t of large U the exact result of the atom ic lim t is reproduced¹⁰. A lthough the above computational scheme looks at rst sight som ewhat di cult to handle, this is not really the case. In fact, t allows us to calculate the self-energy directly without having to do a num erical analytic continuation or an interpolation in k space. Therefore we obtain for t a high resolution in energy and m on entum. In the num erical calculations we have done, we assumed a param agnetic ground state since the antiferrom agnetism is suppressed away from half-lling. W henever possible we have m ade com parisons with Q uantum M onte-C arlo (QMC) results and the agreem ent was always very satisfactory.

In Fig. 1 the momentum dependent excitation spectrum is shown in the underdoped case for U = 8 (in units of the nearest-neighbor transfer integral) and T = 0.0 ne notices an empty upper Hubbard band centered around the M point and a at quasiparticle band crossing the Ferm i energy $_F$. There is also incoherent spectral density near the point resulting from the lower Hubbard band. A los shown are QMC results for nite temperatures⁵. Results for the Ferm i surface are shown in Fig. 2. For n = 0.95 (underdoped case) a hole-

like Ferm i surface is obtained. Due to a collapse of the lower Hubbard band the portion of the at band around the X points sinks below the Ferm i level. In the overdoped regime the Ferm i surface is electron-like. It is seen that Luttinger's theorem ¹³ does not apply here. These results agree with the ones obtained from the DCA⁶.

By taking numerical derivatives of $_{k}(z)$ we have determined the momentum dependent e ective mass m $_{k} = 1$ @Re $_{k}(0^{+})=$ @! in the underdoped regime (see Fig. 3). To our know ledge this is something which could not be done before. For doping less than 2 % m $_{k}$ changes strongly between the minimum value at the M point and the maximum value at the X point, while for dopings larger than 2 % the momentum dependence of m $_{k}$ is weak with a maximum at and not at X as in the underdoped regime. Most important is the strong dependence of m $_{k}$ near the X point on the chosen step size ! when the derivative is taken. This is a clear signature of M FL behavior. Because of the numerical derivative taken of Re $_{k}$ at ! = 0 we obtained a nite value of m $_{k}$ In ! instead of a divergency. In fact, in the limit of vanishing hole doping (half-lled case) we nd a typical M FL behavior of $_{k}(z)$ for U = 8 and k = (=2; =2) like in the weak interaction limit. This is shown in Fig. 4 where the two cases are compared. Because of these features we conclude that for U = 8 and doping less than 2 % M FL theory applies, while for doping concentrations of m one than 2 % norm al Fermi liquid theory is valid.

The di erent nature of the states for doping concentrations $_{\rm h} < 0.02$ and $_{\rm h} > 0.02$ is clearly seen in the density of states (DOS) presented in Fig. 5 for U = 8. Consider inst the case $_{\rm h} < 0.02$. With increasing doping concentration spectral density is shifted from the lower to the upper Hubbard band, or more generally to higher energies. As a consequence the peak in the DOS remains at $_{\rm F}$, i.e., it does not shift for small doping concentrations. Therefore the self-energy has to good approximations the same frequency dependence as for half-lling. This is the origin of MFL behavior. When $_{\rm h} > 0.02$ the lower Hubbard band has essentially collapsed and the peak in the DOS moves away from $_{\rm F}$. In that case conventional Ferm i liquid behavior sets in. This occurs in a rather discontinuous way. This is seen from the phase diagram shown in Fig. 6. The MFL regime with a still existing lower Hubbard band is separated by a region in which two self-consistent solutions are found from

the one with a collapsed lower H ubbard band. One m ay consider that transition as one from quasi-localized electrons to fully itinerant ones. Note that when $_{\rm h} < 0.01$ the M FL regime is divided into two regimes. The two solutions found are only slightly dimension in the amount of the reduction of the lower H ubbard band. For wed value of $_{\rm h}$ the discontinuous behavior of the self-energy as function of U in plies that Luttinger's theorem 13 is not applicable. For U < 6.5 the M FL behavior at half-lling changes sm oothly to a Fermi liquid state.

In sum mary, by using the SCPM we could calculate the zero-temperature self-energy $_{k}$ (z) for the 2D Hubbard model with high resolution with respect to ! and k. We ind a MFL like behavior for quite a large range of hole doping concentration and U. We obtain there a strong momentum dependence of the elective mass. In cases where a comparison with nite temperature results³⁶ can be made the agreement is good. When U > 65 a discontinuous change takes place with increasing hole concentration from more localized electrons with a lower Hubbard band to fully itinerant ones. In the latter case the lower Hubbard band is absent. It is precisely the transfer of spectral density from the lower Hubbard band to higher energies which results in MFL behavior at low hole concentrations. Above the upper discontinuity lines Luttinger's theorem is not applicable. Very close to half-lling long-ranged antiferrom agnetic correlations are expected to modify the present results. Those correlations have been neglected here.
