Fully Frustrated Cold Atoms

M arco Polini, Rosario Fazio, A.H. MacDonald, and M.P. Tosi NEST-INFM and Classe di Scienze, Scuola Normale Superiore, I-56126 Pisa, Italy Physics Department, The University of Texas at Austin, Austin, Texas 78712

(Dated: March 22, 2024)

Fully frustrated Josephson Junction arrays (FF-JJA's) exhibit a subtle compound phase transition in which an Ising transition associated with discrete broken translational symmetry and a Berezinskii-K osterlitz-Thouless (BKT) transition associated with quasi-long-range phase coherence occur nearly simultaneously. In this Letter we discuss a cold atom realization of the FF-JJA system. We demonstrate that both orders can be studied by standard momentum-distribution-function measurements and present numerical results, based on a successful self-consistent spin-wave approximation, that illustrate the expected behavior of observables.

PACS num bers: 03.75 Lm

The preparation of cold atom ic gases trapped in an optical lattice has opened up attractive new possibilities for the experim ental study of strongly correlated many-particle systems [1] and has inspired much theoretical activity (see e.g. Ref. 2 for a review). In particular, the experim ental observation by G reiner et al. [1] of a Super uid-M ott Insulator (SI) transition in a three-dim ensional (3D) optical lattice explicitly dem onstrated the possibility of realizing strongly-correlated cold bosons. The SI transition in an optical lattice was predicted in Ref. 3 and can be described by the Bose-Hubbard model [4], which has also been employed to model 2D granular superconductors [5] and JJA's [6]. This success has motivated many new proposals [7] for cold-atom simulations of strongly correlated boson phenom ena.

In this Letter we propose that cold atom s be used to study the incompletely understood phase transitions that occur in FF-JJA's [6, 8]. The boson Hubbard model for JJA's accounts for Cooper pair hopping between small superconducting particles and for Coulomb interactions which can be dominantly intra-particle. For superconducting particles the model applies when the thermalenergy k_B T is much smaller than the bulk energy gap, i.e. when the underlying ferm ionic character of electrons is suppressed. Cold atoms in optical lattice potentials provide, in som e senses at least, a closer realization [1, 3] of the boson Hubbard model because other degrees of freedom are more completely suppressed and because the interactions are more dominantly on-site. Frustration [8] can be introduced into JJA's by introducing an external m agnetic eld to change the energetically preferred phase relationship between boson amplitudes on neighboring sites. Frustration in this case refers to the impossibility

of choosing the optim alphase dierence for each bond. In a cold atom optical lattice system, frustration can be introduced by altering the phase factors for atom hopping between optical potential minima more explicitly, for example by following procedures similar to those proposed recently by Jaksch and Zoller [9], Mueller [10], and S rensen et al. [11]. The laser congurations suggested in these papers also enable spatially periodic modulation of the magnitude of boson hopping amplitudes, a feature that is important to the proposal outlined below.

In a FF square-lattice JJA the sum of the optimal phase di erences for individual bonds around every plaquette is , fully incompatible with the integer multiple of 2 phase winding constraint imposed by the singlevalued condensate wavefunction. For square lattice JJA's full frustration can be introduced by applying an external magnetic eld that generates one half of a superconducting ux quantum through each plaquette of the array. In the Landau gauge the frustration is in posed by changing the sign of every second vertical hopping parameter. For a FF-JJA, the Gross-Pitaevskiim ean-eld equation of the corresponding boson Hubbard model has two distinct degenerate solutions, illustrated schematically in Fig. 1, which break the discrete translational sym metry of the lattice, and for each solution a free overall phase factor in the condensate wavefunction which breaks gauge symmetry. The surprising property of FF square lattice JJA's, and by extension of FF square lattice cold atom s, is that the Ising order and the quasi-long-range phase order appear to vanish nearly simultaneously and continuously at a com m on critical tem perature. W hen quantum uctuations are included, sim ilar phase changes are expected to occur at zero tem perature as the on-site interaction strength is increased. If these orders do in fact disap-

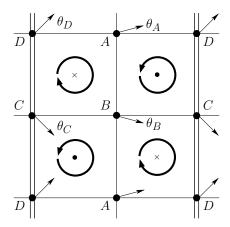

FIG. 1: G round-state degenerate solutions for a classical FF-JJA. D ouble vertical lines stand for m odulated \antiferromagnetic" bonds ($E_{\rm J}$) while single vertical and horizontal lines stand for unm odulated \ferromagnetic bonds" ($E_{\rm J}$). The con guration shown corresponds to =0.5 for which $_{\rm A}$ = $_{\rm B}$ = =12 and $_{\rm D}$ = $_{\rm C}$ = =4. The distinct con guration with equal energy is obtained by ($_{\rm A}$; $_{\rm D}$)! ($_{\rm A}$; $_{\rm D}$) or equivalently by vertical translation by one lattice constant.

pear simultaneously, the phase transition would have to be in a new universality class and could not have a natural description in terms of the condensate wavefunction order-parameter, a situation reminiscent of the deconned quantum critical behavior discussed recently [12] by Senthilet al.

The compound phase change in a frustrated JJA is closely related to the phase changes that occur in the vortex lattices of the mixed state of superconductors, and in rotating ⁴He and cold atom systems [13, 14]. The vortex lattice ground state has broken translational sym metry instigated by frustrating order-parameter-phase dependent terms in the Hamiltonian. The key dierence between vortex lattices and frustrated JJA's is that the broken translational symmetry is discrete rather than continuous in the latter case. Therm al uctuations of a vortex lattice imply [15] that quasi-long-range phase order cannot exist at any nite temperature in 2D system s. For superconductors it has been argued [16] that given the absence of phase coherence, broken translational sym m etry will not occur either. For the FF-JJA case, the opposite conclusion has been reached in a careful M onte Carlo study by O lsson [17]; he nds that that vortex position uctuations suppress the phase sti ness and instigate a BKT transition as the Ising phase transition temperature is approached from below. If correct, this conclusion would have to be altered when frustration

is weakened, as described below, and the Ising transition temperature is driven to zero. In this Letter we point out that these subtle phase changes can be studied by measuring the momentum distribution function (MDF) of a FF cold atom cloud, and report on theoretical estimates for the MDF based on a self-consistent harm onic approximation (SCHA) [18].

We assume that atom hopping between sites on the optical lattice is weak enough to justify a single-band W annier basis [3] with W annier function w (x). The lattice H am iltonian we study is

$$\hat{H}_{f} = \frac{U}{2} \sum_{x_{i}}^{X} \hat{n}_{x_{i}}^{2} \qquad \sum_{x_{i};}^{X} \sum_{x_{i};}^{U} \cos(\hat{x}_{i} \hat{x}_{i+}) \qquad (1)$$

where $x_i = d(n; m)$ with n; m 2 [N; N) is on a 2D square lattice with lattice constant d, is the vector connecting a lattice site to its neighbours, and the Josephson energy or atom hopping energies E_{xx}; are identical (equal to E J) on all bonds except the vertical bonds on every second column. These modulated frustrating bonds have the value E_J with > 0 [18]. In Eq. (1) the phase operator \hat{x}_i has been introduced by approxim ating the atom annihilation operator on site x_{i} by \hat{b}_{x_i} , \hat{b}_{x_i} , \hat{b}_{x_i} , \hat{b}_{x_i} , allowed when the mean occupation n on each lattice site is large. The density \hat{n}_{x_1} and phase \hat{x}_i operators are canonically conjugate on each site. The negative hopping parameters introduce frustration, which can be energetically weakened [18] by choosing < 1.

When quantum uctuations are neglected, the T = 0 condensate phase pattern [8] is determined by minimizing the classical energy with respect to the phase dierence across positive E $_{\rm J}$ links; the single-valued condition requires that the magnitude of the phase dierence across negative E $_{\rm J}$ links 0 = 3 , in plying [8] that sin () = sin (3) and hence that

$$= \arcsin \left(\frac{p}{(3 - 1)} \right) = -2$$
 (2)

for > 1=3, while = 0 for < 1=3. For < 1=3, the energy penalty of frustration is paid completely on the negative E_J link and the classical ground ground state condensate phase is spatially constant. As increases beyond this value, the energy penalty of frustration is increasingly shifted to the positive E_J links. The ground state con guration in this regime is doubly degenerate with currents circulating in opposite directions around alternating plaquettes, as illustrated in Fig. 1. Therm al

and quantum uctuations will degrade both Ising and phase coherence orders.

Phase coherence of cold atoms in an optical lattice can be directly detected by observing a multiple matterwave interference pattern after ballistic expansion with all trapping potentials switched o. As time evolves, phase-coherent matter waves that are emitted from each lattice site overlap and interfere with each other. Narrow peaks appear in the MDF due a combination of lattice periodicity and long-range phase coherence [19, 20, 21]. The vortex superlattice of the > 1=3 mean-eld state results in the appearance of additional peaks in the MDF; $n_f(k) = \langle eh^{\gamma}(k) \hat{k} \rangle i=A$ where A is the system area, and $\hat{k} = 2$ four ier transform of the eld operator, $\hat{k} = 2$ four ier transform of the eld operator, $\hat{k} = 2$ for $\hat{k} = 3$ follows that

$$n_{f}(k) = \frac{n_{j} w(k)_{j}^{2}}{A} < e^{X} e^{ik(x_{i} x_{j})} C(x_{i}; x_{j})$$
(3)

where we have de ned a W annier function form factor w (k) = $d^2x e^{ik \cdot x}w$ (x) and the phase-phase correlator C $(x_i; x_j)$ hexp $[i(x_i \quad x_j)]i$. In the broken translation sym m etry state n_f (k) is non-zero at superlattice reciprocal lattice vectors $G_{n,m} = (n,m)=d$; for the classical (i.e. U=0) ground state at zero temperature we not that n_f (G) = $(N_s^2=A)njw$ (G) f^2S_0 (G) where $N_s=4N^2$ is the total number of lattice sites, and the superlattice structure factors are

$$S_0 (G_{0;0}) = [\cos () \cos (=2)]^2$$

 $S_0 (G_{1;0}) = [\sin () \sin (=2)]^2$
 $S_0 (G_{0;1}) = [\sin () \cos (=2)]^2$
 $S_0 (G_{1:1}) = [\cos () \sin (=2)]^2$ (4)

with S_0 ($G_{n+2k,m+2k}$) = S_0 ($G_{n,m}$) for any integers n, m, and k. Phase coherence in a lattice leads to condensation peaks in n_f (k) at all reciprocal lattice vectors $G_{2n;2m}$. Coherence and Ising broken translational sym m etry leads to additional peaks (satellites) w ith the characteristic pattern of structure factors sum m arized by Eqs. (4) at the 2 2 superlattice reciprocal lattice vectors. M DF m easurem ents therefore probe both types of order.

These results will be altered by both quantum and thermal uctuations. At low temperature ($k_B T E_J$) and well inside the super uid regime ($U E_J$), the phase correlation functions are given reliably by a SCHA [18] in which the density matrix is approximated

by that of an elective harm onic model delened by mean condensate phases on each site and harm onic coupling constants K on each nearest neighbour link. Minimizing the variational free-energy with respect to mean phases enforces average current conservation at each node of the lattice. Minimization with respect to the harmonic coupling constants sets them equal to the self-consistently determined mean curvature of the Josephson interaction. The phase changes across the vertical and horizontal positive E J links, hand v, are unequal in this approximation, as are the harmonic coupling constants K hand K v and (of course) the coupling constant on frustrated links K . For U ! 0 and T ! 0, the he v ! , K he K v ! E J cos and K ! E J cos (3).

The SCHA phase correlation function C $(x_i; x_j) = C_{NF}; C_Q; (X_i; X_j)$ is the product of a long-range factor $C_{NF}; dependent only on position within the 2 2 brokensymmetry unit cell, and a Gaussian factor <math>C_Q; (X_i; X_j)$ which captures the power-law decay of phase correlations in 2D super uids (here X_i is a lattice vector of the large unit cell so that sites are labelled by and i). We not that C_{NF} is given by

$$C_{NF} = \begin{bmatrix} B & e^{i v} & e^{i(v+h)} & e^{i h} & 1 \\ B & e^{i v} & 1 & e^{i h} & e^{i(h+v)} & E \\ e^{i(v+h)} & e^{i h} & 1 & e^{i(v+2h)} & 1 \end{bmatrix};$$

$$e^{i h} & e^{i(h+v)} & e^{i(v+2h)} & 1$$
(5)

and that

$$C_{Q}'(X_{i};X_{j}) = \exp \left[\frac{U}{N_{s}^{2}}X X \frac{F_{k}'(X_{i} X_{j})}{k_{s}}\right]$$

$$[1 + 2N_{BE}(k_{s} = k_{B}T)] : (6)$$

In Eq. (6) the sum is over the four Bogoliubov eigenmodes of the harm onic Josephson term at each wavevector in the 2 super cell's Brillouin zone. Because we have chosen strictly on-site interactions, the quantum harmonic problem can be solved by rst diagonalizing the Josephson interaction term, as in the classical case, and then performing independent Bogoliubov transformations on each mode. The contribution of a given Bogoliubov mode to the mean square phase dierence between sites (;i) and (;j) in Eq. (6) is therefore characterized by the quantity [18]

$$F_{k}$$
; $(X_{i} \ X_{j}) = \dot{y} (k) \dot{f} + \dot{y} (k) \dot{f} 2 < e [v (k)]^{2}$
 $v (k) e^{ik} (X_{i} \ X_{j} + b)$ (7)

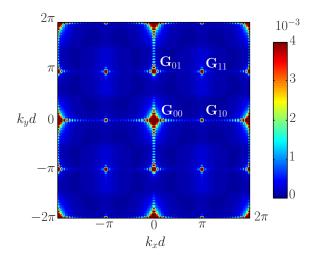

FIG .2: The structure factor S (k) for FF cold bosons in a 2D array with = 0.5 as a function of the continuous variable kd 2 [2 ;2] [2 ;2]. Here T = 0.242E $_{\rm J}$ =k $_{\rm B}$ [22], and U = 0.1E $_{\rm J}$.

where b is the site separation for i = j, $N_{BE}(x)$ is a Bose-Einstein thermal factor, $k_{ij}^{2} = U_{ik}$, k_{ij} , and $V_{ik}(x)$ being the eigenvalues and the -th component of the eigenvectors of the harm onic Josephson interaction.

We have evaluated S (k) = $n_f(k)A = (nN_s^2) \dot{y}(k) \dot{f}$) in the presence of both quantum and thermal uctuations by sum ming over a nite lattice with $N_s = 1296$ sites in Eq. (3) and applying periodic boundary conditions to make the wavevectors in Eq. (6) discrete. A typical result is reported in Fig. 2. The presence of non-zero Ising satellites at $k = G_{1;0}$; $G_{0;1}$ and $G_{1;1}$ is evident. These peaks are a sharp manifestation of the broken discrete translational symmetry and would be absent in an unfinstrated system .

The evolution of S(k) with U at xed T = $0.242\,\mathrm{E}_{\mathrm{J}}$ =k_B is illustrated in Fig. 3 where we plot S(G) for G_{0;0}, G_{1;0}, G_{0;1} and G_{1;1}. All four peaks are slightly suppressed by quantum and thermal uctuations with respect to the U = T = 0 values in Eq. (4). At the critical value U_{IS} 0:14 the Ising satellites disappear while the condensation peak survives (the rst order character of this transition is an artifact of the SCHA). The superlattice peaks may be regarded as Ising order parameters S = sin (h) (see Eq. (4)). At the Ising point h ! 0, causing S(G_{0;0}) to increase with increasing U, before resuming its decline.

In sum mary, we have shown that FF cold atoms can o er a unique opportunity for experimental study of a system in which there is competition between critical phenomena associated with $\rm Z_2$ and gauge U (1) broken

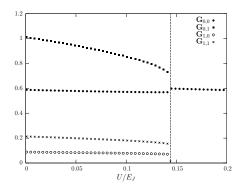

FIG. 3: Condensation and Ising peaks of the structure factor S (G) as a function of U=E $_{\rm J}$. The value of S (G) for G $_{\rm 1,0}$, G $_{\rm 0,1}$ and G $_{\rm 1,1}$ has been multiplied by a factor of 10 for clarity. The vertical dashed line indicates the value of U $_{\rm IS}^{\rm c}$.

- [22] This value of T has been chosen to be slightly below the Ising critical tem perature $T_{\rm IS}^{\rm c}$ for U = 0 just for computational convenience. In fact the only requirement on T to observe the Ising peaks in a MDF measurament is $T < T_{\rm IS}^{\rm c}$. As T decreases, the critical value $U_{\rm IS}^{\rm c}$ for an Ising transition in the presence of interactions rapidly increases.
