#### A bstract

We report di usion M onte C arb (D M C) calculations on M gO in the rock-salt and C sC l structures. The calculations are based on H artree-Fock pseudopotentials, with the single-particle orbitals entering the correlated wave function being represented by a system atically convergeable cubic-spline basis. System atic tests are presented on system -size errors using periodically repeating cells of up to over 600 atom s. The equilibrium lattice parameter of the rock-salt structure obtained within DM C is alm ost identical to the H artree-Fock result, which is close to the experimental value. The DM C result for the bulk m odulus is also in good agreement with the experimental value. The B1-B2 transition pressure (between the rock-salt and C sC l structures) is predicted to be just below 600 G Pa, which is beyond the experimentally accessible range, in accord with other predictions based on H artree-Fock and density functional theories.

# 1 Introduction

The quantum M onte C arb (QMC) technique is becoming an increasingly important tool in the study of condensed m atter [1]. Competitive in accuracy with high-level quantum chemistry methods, it has the enorm ous advantage of being practicable for large systems containing hundreds of atoms. The power of QMC in overcoming the de ciencies of density functional theory (DFT) has been amply demonstrated by recent applications, including the energetics of point defects in silicon [2] and carbon [3], the reconstruction of the Si (001) surface [4] and its interaction with  $H_2$  [5], and the calculation of optical excitation energies [6]. Nevertheless, the classes of materials to which QMC has been applied have so far been rather limited. O xide materials are likely to be a very fruitful eld for the application of QMC, but in exploring this eld it is clearly important to study the capabilities of the techniques for the simplest possible oxides. We present here QMC calculations on M gO, focusing on its elementary bulk properties, including the equilibrium lattice parameter of the rock-salt structure, the stable structure under ambient conditions, and the pressure of the B1-B2 transition between the rock-salt and C scl structures.

Two types of QMC are relevant here. In the rst, known as variational M onte Carlo (VMC), a trial m any-electron wave function is constructed as the product of a Slater determ inant of single-electron orbitals and the so-called Jastrow correlation factor. The latter is parameterised, and the parameter values are obtained using a stochastic optim isation procedure. Since VMC by itself is not usually accurate enough, the optim ised m any-electron wave function produced by VMC is then used in di usion M onte C arlo (OMC) [1, 7], which improves the ground-state estim at by perform ing an evolution in imaginary time. In

principle, the ground-state energy would be exact, but to overcome the ferm ion sign problem we use the standard \ xed-node approximation" [8]. In practice, only the valence electrons are treated explicitly, the interactions between the valence and core electrons being represented by pseudopotentials. This introduces additional approximations, including the \pseudopotential locality approximation". The calculations are performed on periodically repeated cells, and system size errors need to be carefully treated. However, in many cases, the overall errors within QMC can be made much smaller than those within DFT, and QMC has already been important in revealing, quantifying and overcoming DFT errors in such quantities as defect formation energies, surface reaction energies and energy barriers [2, 3, 5].

The three main purposes of this work are: rst, to establish the technical feasibility of performing QMC on MgO; second, to study di erences between DFT and QMC predictions for the properties of bulk MgO; and third, to prepare the way for QMC work on more challenging oxides. As one of the simplest oxides, MgO has often been used as a paradigm for testing theoretical techniques. For QMC, the issue of technical feasibility is a non-trivial one, since the computing e ort required to obtain accurate results with DMC depends heavily on the ability of VMC to deliver wave functions which are su ciently close to the exact ground-state wave function. If su ciently accurate trial wave functions cannot be obtained, the DMC calculations may even becom e unstable. The electronic simplicity of MgO is expected to ease the task of nding good trial wave functions.

The concerns of this work are not purely technical. The pressure-induced transition from the rocksalt to C sC l structure in M gO has been much studied because of its geological interest (see, e.g., [9, 10] and references therein). We also expect that the present work will provide the basis for applying QM C to several important and controversial questions related to ionic materials such as M gO, including the adsorption and dissociation of m olecules on their surfaces (see, e.g., R ef. [11]), the self-trapping of hole centres and their trapping at defects (see, e.g., R ef. [12]), and the con-ict between theory and experiment for the slope, dT=dp, of their melting curves [13, 14, 15, 16]. Beyond this, we hope that the experience gained here will help to prepare the way for the application of QM C to transition-m etal oxides such FeO, where electron correlation is highly non-trivial. DM C studies of N io [17] and M nO [18] have already show n the feasibility of calculations on these materials, but those studies did not include energy-volum e curves, and the unit cells used were not large enough to give the accuracy required here.

In the following Section we summarise the QMC techniques used here. In Sec. 3, we present tests on the magnitude of various errors, including system -size errors, and we report our results for the total energy as a function of volume for the rock-salt and C sC l structures, and the transition pressure between the two. D iscussion, prospects for future work, and conclusions are presented in Sec. 4.

### 2 Techniques

Detailed descriptions of VMC and DMC have already been reported [1], so here we only outline rather brie y the main features of the present work. All the QMC calculations presented here were performed using the casino code, the technical details of which are given in Ref. [19].

Our trial wave functions are of the Slater-Jastrow type:

$$_{\rm T}$$
 (R) = D  ${\rm D}^{\rm \#}{\rm e}^{\rm J}$ ; (1)

where D " and D <sup>#</sup> are Slater determ inants of up- and down-spin single-electron orbitals, and  $e^{J}$  is the so-called Jastrow factor, describing the correlation between the electrons. We use single-electron orbitals obtained from DFT calculations. These single-particle orbitals x the nodal surface (the surface in conguration space on which the wave function vanishes and across which it changes sign). Within this \ xed-node approximation" DMC gives a variational upper bound to the ground state energy, rather than the exact ground state energy. However, because of its large band-gap, we expect that a single Slater determ inant will give a good description of the nodal surface of M gO. The function J appearing in the Jastrow factor is a sum of parametrized one-body and two-body terms [20], the latter being designed to satisfy the cusp conditions. The free parameters in J are determ ined by requiring that the variance of the local energy in VMC be as small as possible [21, 22]. In the present work, the m any-body wave function represents explicitly only valence electrons, whose interactions with the ionic cores are represented by pseudopotentials. W e used pseudopotentials generated within Hartree-Fock (HF) theory, but including scalar relativistic e ects [23]. There is evidence to show that HF theory provides better pseudopotentials for use within QMC than DFT [24]. The core radii of our pseudopotentials are r(0.2s) = 0.423 A, r(0.2p) = 0.397 A, r(0.3d) = 0.524 A, r(M g3s) = r(M g3p) = r(M g3d) = 1.259 A.

The single-particle orbitals entering the Slater determ inants of Eq. (1) are the most important component of the wave function. Filippi and Fahy [32] have developed a method for optim ising orbitals within VMC, which achieved an energy reduction in diam ond from optim ising LDA orbitals of 0.040 (16) eV per atom. Kent et al. [25] found that in bulk silicon using LDA orbitals in a VMC calculation gave an energy 0.024 (4) eV per atom lower than HF orbitals. These energy changes would be significantly reduced in DMC and it appears that HF and LDA orbitals are su cient for these systems. In this work we have used LDA orbitals obtained using the plane-wave pseudopotential DFT code pw scf [26].

The basis set used to represent the single-particle orbitals in the QMC calculations them selves is not plane-waves, which become very ine cient for large systems, because the computation cost of evaluating an orbital is proportional to the system size. Instead, we use a B-spline basis, also known as blip functions, consisting of piecew ise continuous localised cubic spline functions centred on a regular grid of points. A detailed explanation of blip functions, and their great advantages for QMC calculations has been reported elsewhere [27]. The blip basis is closely related to a plane-wave basis, and for a plane-wave cut-o energy  $E_{cut} = h^2 k_{cut}^2 = 2m$  (m is the electron mass), there is a natural choice of blip-grid spacing a given by  $a = -k_{cut}$ . In the same way that plane-wave convergence is achieved by increasing  $k_{cut}$ , blip convergence is achieved by reducing a. Because of the relationship between plane-waves and blips, it is straightforw and to transform the plane-wave coe cients from the pw scf calculations into the blip coe cients needed for the QMC calculations, as explained in more detail in our earlier paper [27].

For QMC calculations on perfect crystals, there is a useful device which allows a considerable saving of memory. Instead of constructing single-particle orbitals at a given k-point (e.g., the point) for the large repeating cell, we construct them for the primitive cell at the corresponding set of k-points. The plane wave coe cients from this calculation are then converted to blip coe cients on points of the blip-grid within the primitive cell. At run-time, a simple conversion allows these stored coe cients to be used to calculate the required values of the single-particle orbitals at any point in the large repeating cell. The key point here is that it is unnecessary to store blip coe cients at grid points covering the entire large repeating cell.

An important source of error in QMC calculations using periodic boundary conditions is the limited size of the repeating cell, and the convergence of the QMC energy with respect to the size of the sin ulation cell must be carefully investigated. To improve this convergence, we follow the common practice [33] of correcting for this error by using separate DFT calculations: we add to the DMC energies the di erence  $E_{-k}$  between the DFT-LDA energy calculated with a very large set of k-points and the DFT-LDA energy calculated using the same sampling as in the DMC calculation. The question of correcting for nite size errors in the C oulomb energy has been addressed in recent papers [28, 29, 30], and a method known as the model periodic C oulomb (MPC) interaction has been developed. The nite size error in the Ewald interaction energy arises from the exchange-correlation energy, which can be written as the interaction of the electrons with their exchange-correlation holes. The interaction with the hole should have the standard 1=r form, but within periodic boundary conditions this must be replaced by a periodic interaction. The MPC interaction maintains the correct Ewald interaction for evaluating the H artree energy while for the exchange-correlation energy a periodically repeated potential based on the 1=r form is used. This signi cantly reduces the nite size errors in the interaction energy, although e ects due to the squeezing of the exchange-correlation hole into a nite cell still remain.

W e also mention two other technical points relating to size e ects. DMC calculations require the use of real trial wave functions. However, these can be constructed using single-particle orbitals obtained either from calculations at the -point or, in general, k-points which correspond to one half of a reciprocal lattice vector of the simulation cell [31]. The di erence between QMC energies obtained in these two ways can be used as an indication of the system size errors. The other point is that a given physical crystal structure

can be treated using large repeating cells associated with di erent B ravais lattices. Since M gO in both the rock-salt and C sC l structures has cubic sym m etry, it is m ost natural to use B ravais lattices for the repeating cell having sim ple-cubic (sc), body-centred-cubic (bcc) or face-centred-cubic (fcc) sym m etries. W e expect that the fcc repeating geom etry will give the best convergence with respect to system size, and we shall present results which illustrate this e ect.

The number of walkers in DMC simulations is governed by a population control algorithm, which has the purpose of maintaining this number roughly constant. In order to minim is statistical bias in the total energy, the calculations need to be run with a large population of walkers. For our DMC calculations we have used a target population of 640 walkers, which also makes it e cient to run on massively parallel machines, with parallelism achieved by distributing walkers across processors. For the imaginary time evolution of the walkers we found that a time step of 0.005 a.u. gave time step errors in the DMC energy of less than 10 m eV /atom.

## 3 Results

### 3.1 Technical tests

We have found that the quality of our Slater-Jastrow trial wave function is in proved if a large plane-wave cut-o is used in generating the single-particle orbitals, and a correspondingly smallblip-grid spacing is used in representing them. In order to investigate this question, we perform ed a series of VMC calculations, and calculated the standard error in the energy as a function of plane-wave cut-o. The blip-grid spacing was taken to be related to the plane-wave cut-o by the hatural' form ula mentioned in Sec. 2. The calculations were performed without a Jastrow factor, because this makes it possible to check some components of the total energy against DFT calculations. These calculations were performed on a 16-atom cell for M gO in the rock-salt structure with a lattice parameter of a = 4:17 A, which is close to the zero pressure equilibrium lattice parameter. Results are presented in Fig. 1. We notice that by increasing the PW cuto from 680 eV to 6800 eV the standard error in the energy is reduced by a factor of 2. This means that QMC runs performed using the trial wave function obtained with the largest cuto can be 4 times shorter, in order to achieve the same e statistical accuracy. M ore importantly, we found that using a very large PW cuto was essential for having stable DMC runs. We were unable to perform any useful DMC simulation with cuto energies less than 2712 eV.

We have made extensive tests on system size e ects. We divide our discussion of these tests into two parts: rst, tests on the rock-salt structure at low pressures, which are relevant to the equilibrium properties of this structure; second, tests on both the rock-salt and C sC l structures at high pressures, which are relevant to the determ ination of the transition pressure. A swe shall see, these two sets of tests involve som ewhat di erent questions. In Fig. 2, we show the VM C energy per atom of M gO as a function of the number of atom s in the repeating cell, using both the standard Ewald interaction and the M PC interaction. For these calculations we used a plane-wave cut-o of 6800 eV and the associated natural blip-grid spacing for the description of the single-particle orbitals. We note that the M PC results appear to converge considerably faster than the Ewald ones, and that for a system of 54 atom s the M PC energy is already converged to better than 50 m eV/atom. We therefore decided to use this cell size to evaluate the energy-volum e curve presented in the follow ing section.

The results we report here for the C sC l structure were performed with the standard Ewald method rather than the MPC method. In order to check system -size errors thoroughly, we found it essential to perform tests on large system s of up to over 600 atom s. We made extensive tests on the C sC l structure to compare sc and for repeating geometries and to exam ine the e ect of using di erent sam pling wavevectors. The sam pling wavevectors we used are the -point (2 =L)(0;0;0), and the wavevector (2 =L)(0:5;0:5;0:5), where L speci es the dimension of the repeated cell. (In more detail, L is the length such that with sc repeating geometry the primitive translation vectors are L (1;0;0), L (0;1;0) and L (0;0;1), while with for geometry they are L (0;0:5;0:5), L (0:5;0:5) and L (0:5;0:5;0).) Since the wavevector (2 =L)(0:5;0:5;0:5) lies on the zone boundary of the Brillouin zone associated with the periodically repeated supercell, we refer to sam pling using this wavevector as \zone-boundary" sam pling. These tests were perform ed at the

volum e 8.77 A<sup>3</sup>/atom, which is close to the zero pressure equilibrium volum e. The tests were all perform ed using VMC, and we used the Jastrow factor optim ised using a 16 atom cell for all system sizes, because re-optim ising the Jastrow factor introduces sm all \jumps" in the energy. Since we needed to go to large system sizes, we decided to reduce the plane-wave cut-o from 6800 eV to 2712 eV, because this gave a considerable reduction in the mem ory required; with this lower cut-o, the standard error in the energy uctuations is only slightly larger (see Fig. 1), and DMC calculations are still stable. Results of these tests are shown in Fig. 3. We see that convergence to within less than 50 meV /atom is obtained for system s larger than 108/128 atom. We also note that convergence is better with the fcc than with the sc repeating geom etry, as expected, and that there is little to choose between -point and \zone-boundary" sam pling. We have therefore perform ed all further calculations using fcc geom etry and -point sam pling.

Since calculation of the transition pressure requires QMC calculations for the two structures at high pressures, we have perform ed further VMC calculations at volum es 4.23 and 4.41 A  $^3$ /atom for the CsC land the rock-salt structures respectively, close to the transition, using the Ewald interaction. Results of these tests are reported in Table 2. We see that for calculations on the CsC l structure, using a cell containing 108 atom s with fcc repeating geom etry, the error is about 50 m eV /atom. The error is approximately the same for the rock-salt structure with a 128-atom cell, so that the error in the energy di erence between the two structures is less than our target accuracy of 30 eV /atom.

#### 3.2 Production results

In Fig. 4 we display DMC energies as a function of volume for M gO in the NaCl structure. The length of these simulations was typically 6000 steps, resulting in a statistical error bar of less than 10 m eV / atom. These energy points were then used to t the parameters of the B irch-M urnaghan equation of state [53]:

$$E = E_{0} + \frac{3}{2}V_{0}B_{0} \quad \frac{3}{4}(1+2) \quad \frac{V_{0}}{V} \quad \frac{4=3}{2} \quad \frac{V_{0}}{V} \quad \frac{2}{3}(1+2) \quad \frac{V_{0}}{V} \quad \frac{2=3}{4} + \frac{1}{2} \quad \frac{3}{2}(1+2) \quad \quad \frac$$

 $3B_0^0=4$ ),  $V_0$  is the equilibrium volume,  $B_0$  is the zero-pressure bulk modulus,  $B_0^0$  is its where = (3 derivative with respect to pressure at zero pressure, and  $E_0$  is the energy at the minimum. The tted curve is also reported on the same Figure. The values of the tted parameters are reported in Table 1 together with other theoretical results and experimental data. A comparison of the QMC results with experimental values shows that our calculated lattice parameter of  $a_0 = 4.098$  A is smaller than the m easured value of  $a_0 = 4213 \text{ A}$  [34], and our bulk modulus  $B_0 = 183 \text{ GPa}$  is greater than the measured 2 GPa [34]. However, two kinds of corrections need to be made. It is known from value  $B_0 = 160$ earlier DFT calculations [35] that room temperature them all pressure due to lattice vibrations increases a<sub>0</sub> by 0:03 A and decreases B<sub>0</sub> by 10 GPa. We should also correct for pseudopotential errors. To estimate these, we have compared the predictions of pseudopotential and all-electron HF calculations using the crystal  $[\beta 6]$  code (see Table 1). This shows that the pseudopotentials we have used underestim at  $a_0$  by 0.10 A and overestim ate  $B_0$  by 15 GPa. Combining these two corrections, our revised QMC values are  $a_0 = 4.23$  A and  $B_0 = 158$  GPa, which are very close to the experim ental values.

In Fig. 5 we report the DMC energy for M gO in the NaCl and the C sCl structures evaluated for volum es corresponding to roughly one half of the zero pressure equilibrium volum e, which is the region of volum es in which the transition occurs. These energy points have also been tted to the B irch-M umaghan equation of state, which we have then used to compute the enthalpies of the two structures, which are displayed in the upperpart of Fig. 6, from which we infer a transition pressure of about 597 G Pa. W e note that the slopes of the two curves are very sim ilar, and that an error of about 1 m eV /atom in the relative enthalpy results in an error in the transition pressure of about 1 G Pa. W e do not expect our DM C results to be m ore accurate than about 20 m eV /atom, so our computed transition pressure should be considered to have an error bar of about 20 G Pa. For comparison, we also report in the lower part of Fig. 6 the enthalpy evaluated with DFT-LDA and the same pseudopotentials, from which we deduce a transition pressure of 569 G Pa.

# 4 Discussion and conclusions

An important conclusion from this work is that it is technically feasible to carry out di usion M onte C arb calculations on M gO at the level of accuracy required to com pute quantities such as the equilibrium lattice constant, the bulk m odulus, and the B1-B2 transition pressure. As we mentioned in the Introduction, this is a non-trivial conclusion, because DMC calculations succeed in practice only if the many-body trial wave function is su ciently close to the true ground state wave function. Even though M gO should be a favourable oxide in this respect, it was stillessential to pay careful attention to the accurate representation of the single-electron orbitals in order to bring statistical uctuations under control.

We have shown that, provided corrections are made for thermale ects and errors due to imperfections of our pseudopotentials, the QMC predictions of lattice parameter  $a_0$  and bulk modulus  $B_0$  agree with experimental values to within 0.5% for  $a_0$  and to within experimental error ( 2%) for  $B_0$ . In future work, there should be scope for further in provem ent in the pseudopotentials. It is interesting to note that our QMC prediction for  $a_0$  is almost identical to the HF prediction with the same pseudopotentials. This might seem to suggest that correlation e ects are negligible in M gO. However, this is certainly not the case. The correlation energy is at least the di erence between the HF and the QMC total energies. We nd that for the rock-salt structure near the equilibrium volume, this dierence is 4:5 eV/atom. The close agreem ent between the HF and QMC lattice parameters therefore indicates that this rather large correlation energy depends only weakly on volume.OurQMC value of 597 20 GPa for the B1-B2 transition pressure supports the most recent DFT predictions of a pressure in the region of 500 GPa, which is beyond the region of geophysical interest (the pressure at the core-m antle boundary of the Earth is 135 GPa). The detailed value we have found may su er from a pseudopotential error, but at present we are unable to quantify this.

W ith these encouraging results for M gO, we believe that there are now good prospects for extending QMC m ethods to studying the m ore challenging problems involving M gO m entioned in the introduction, and to studies of transition m etal oxides. LDA (and generalised gradient approximation) calculations are unsuitable for transition m etal oxides because they lead to an incorrect lling of the energy levels. Unrestricted HF and B 3LYP orbitals have already been used with some success in DMC studies of transition m etal oxides consider using LDA + U or SIC (self-interaction corrected) DFT orbitals. Tow ler and N eeds [52] found that unrestricted HF orbitals gave a low er energy than B 3LYP orbitals for N iO. Transition m etal oxides are clearly a case where it would be useful to optim ise the orbitals in the presence of the Jastrow factor.

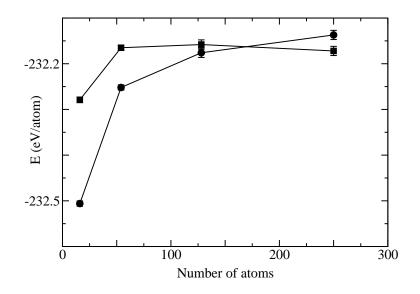

Figure 2: The VMC energy per atom for M gO in the rock-salt structure with a volum e per atom of 9.06 A<sup>3</sup> as a function of the number of atom s in the repeating cell, using both the E wald interaction (circle) and the M PC interaction (squares).

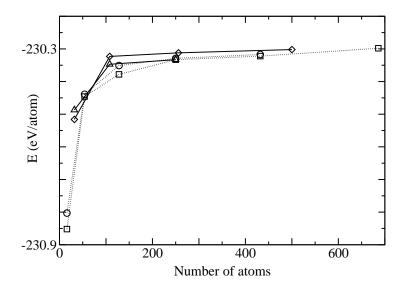

Figure 3: The VM C energy per atom for M gO in the C sC lstructure with a volum e per atom of 8.77 A<sup>3</sup> as a function of the num ber of atom s in the repeating cell, calculated using the E wald interaction. Squares and circles: sim ple cubic cell with -point and zone-boundary sam pling, respectively; diam onds and triangles: fcc cell with -point and zone-boundary sam pling (see text for wavevector used in zone-boundary sam pling). The lines are guides to the eye.

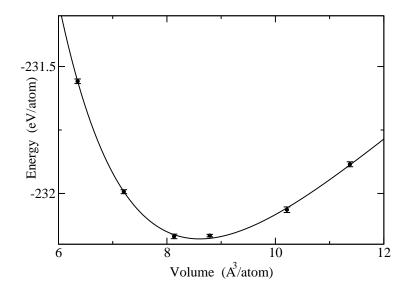

Figure 4: The DMC energy per atom as function of volume for MgO in the NaCl structure.

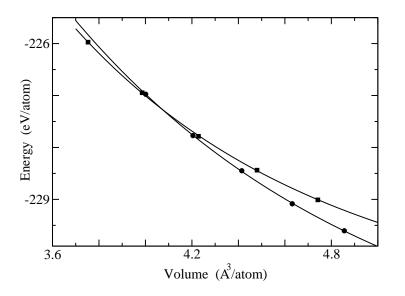

Figure 5: The DMC energy per atom for the NaCl structure (circles) and the CsCl structure (squares) of MgO as a function of volume in the region of the B1-B2 phase transition.

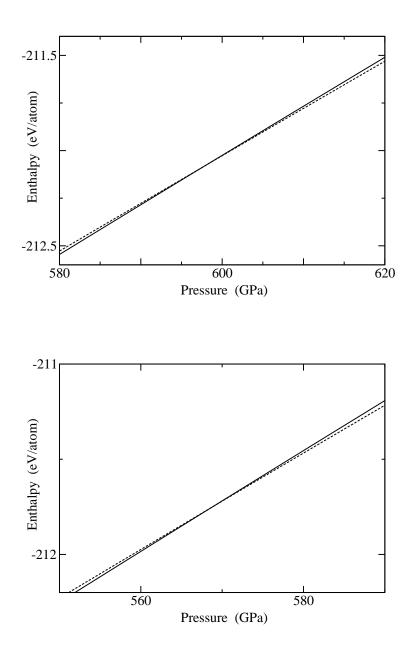

Figure 6: The enthalpy per atom of the NaCland CsCl (dashed line) structures of MgO as a function of pressure. Top picture: t to the DMC data; bottom picture: t to the DFT-LDA data.
