Institute for Materials Research, Tohoku University, Sendai 980-8577, Japan

Magnetic circular dichroism (MCD) of rutile $Ti_{1-x}Co_xO_{2-\delta}$ is systematically examined with various *x* and δ to reveal a phase diagram for the appearance of ferromagnetism at higher carrier concentration and Co content. The phase diagram exactly matches with that determined from anomalous Hall effect (AHE). The magnetic field dependence of MCD also shows good coincidence with those of the magnetization and AHE. The coincidence of these independent measurements strongly suggests single and intrinsic ferromagnetic origin.

Ferromagnetic semiconductors provide an arena for spintronics devices utilizing both charge and spin degrees of freedom of charge carriers.¹ The ferromagnetism can be controlled by electrical or optical stimulus as demonstrated for III-V ferromagnetic semiconductors,^{2,3} but the operation has been limited to temperatures far below room temperature. Therefore, extensive researches have been devoted to search for higher Curie temperature (T_C) ferromagnetic semiconductors. Oxide semiconductor family is one of the most promising host compounds to achieve higher T_C .^{4,5} Indeed, room temperature ferromagnetism was revealed in anatase and rutile Ti_{1-x}Co_xO_{2- δ}.^{6,7} For rutile Ti_{1-x}Co_xO_{2- δ}, anomalous Hall effect (AHE) was shown to emerge above certain thresholds of the electron concentration and Co content. The anomalous Hall conductivity σ_{xy} ^{AHE} scaled with the longitudinal conductivity σ_{xx} as σ_{xy} ^{AHE} $\propto \sigma_{xx}^{1.5-1.7.8}$.

Magneto-optical effect of ferromagnetic semiconductor and AHE are ferromagnetic responses of the photo-excited and dc-driven charge carriers, respectively. Magneto-optical effect and AHE reflect the off-diagonal part of the dielectric tensor, corresponding to the nonzero and zero components of angular momentum, respectively. Among various magneto-optical effects, magnetic circular dichroism (MCD) spectrum is proportional to the energy derivative of the absorption coefficient (α) spectrum,⁹ hence, the absorption threshold should have a good coincidence with MCD spectrum. We have already reported on the ferromagnetic MCD varying systematically on *x* and δ for anatase Ti_{1-x}Co_xO_{2- δ}¹⁰ Rutile Ti_{1-x}Co_xO_{2- δ} was reported to show ferromagnetic MCD,¹¹ although the dependence on the carrier concentration (*n*) and *x* was not investigated systematically. In this paper, we report on the systematic evolution of ferromagnetic MCD in rutile Ti_{1-x}Co_xO_{2- δ} with increasing *n* and *x*, for identical samples used in Ref. 8 so as to make a direct comparison between MCD and AHE.

Rutile $Ti_{1-x}Co_xO_{2-\delta}$ epitaxial thin films were fabricated by laser molecular beam epitaxy.⁸ Ti_{1-x}Co_xO₂ ceramics targets were ablated by focused KrF excimer laser pulses. The films with (101) orientation were grown on r-sapphire substrates at 400 °C. By varying the oxygen pressure during the growth ($P_{\Omega 2}$) from 1×10^{-7} Torr to 1×10^{-4} Torr, δ and consequently *n* can be tuned systematically. The reflection high energy electron diffraction intensity was monitored in situ during the growth. The intensity oscillation was observed at initial stage of the growth, and the surface morphology of the resulting films (70-120 nm thick) showed atomically flat surfaces consisted of the steps and terraces observed by atomic force microscopy. Segregation of secondary phase was not observed under careful inspections by x-ray diffraction, atomic force microscopy, scanning electron microscopy, and transmission electron microscopy. The absorption spectra in visible to ultraviolet region were deduced from the transmittance and reflectance measurements. MCD was measured with the magnetic field normal to the film plane (Faraday configuration).¹⁰ The magnetization was also measured in magnetic field normal to the film plane with a superconducting quantum interference device magnetometer. The Hall effect in magnetic field normal to the film plane was measured for photolithographically patterned Hall bars. n was deduced from the ordinary part of the Hall resistance, that is the linear slope component with respect to the magnetic field. The mobility was approximately the same for all the conducting samples ($\sim 0.1 \text{ cm}^2/\text{Vs}$).

Figure 1 shows the absorption and MCD spectra measured at room temperature for the Ti_{0.97}Co_{0.03}O_{2- δ} with different *n*. The films are mostly transparent in visible region, and α increases from ~3 eV as shown in Fig. 1(a). Only for $n = 1 \times 10^{22}$ cm⁻³ sample, the absorption threshold significantly shifts to higher energy side and the in-gap absorption develops around 1.5 eV. These features are similar to the cases for reduced bulk TiO_{2- δ}.¹² As shown in Fig. 1(b), MCD signal is negligible for lower n (7 × 10¹⁸ cm⁻³, 4 × 10¹⁹ cm⁻³), whereas the large signals appears for higher n (2 × 10²⁰ cm⁻³, 1 × 10²² cm⁻³). The latter spectra are rather broad: MCD is negatively large from 1.5 eV to about the absorption threshold, and turns to be positive for the higher energy region. The in-gap MCD might be caused by the strong spin-orbit coupling.¹³ For $n = 1 \times 10^{22}$ cm⁻³ sample, both the absorption and MCD spectra show the similar amount of blue shift. The inset in Fig. 1(b) shows the MCD spectra for $n = 2 \times 10^{20}$ cm⁻³ sample measured in various magnetic fields. MCD at any photon energy changes in the same manner with magnetic field and saturates in higher magnetic field, indicating that the ferromagnetic MCD is originated from the single ferromagnetic source.¹⁴

Figure 2 shows the *x* dependence of MCD spectra ((a) and (b)) and magnetic field response ((c) and (d)) for conducting Ti_{1-x}Co_xO_{2- δ} samples (grown in different $P_{O2} = 10^{-6}$, 10^{-7} Torr). The MCD signal is negligible for x = 0 and x = 0.01. From x = 0.03, the MCD signal appears and increases with increasing *x*. The magnetic field dependence of MCD signal apparently shows the ferromagnetic behavior for x = 0.03-0.10: the steep increase in low magnetic field and the clear saturation in high magnetic field. The hysteresis is hardly seen in this magnetic field scale. The saturation field depends on P_{O2} : $P_{O2} = 10^{-6}$ Torr samples show steeper increase of MCD than that for $P_{O2} = 10^{-7}$ Torr samples

The present study reveals that the appearance of ferromagnetic MCD depends both on *n* and *x* as mapped out in Fig. 3, where solid and open symbols represent ferromagnetic and paramagnetic MCD responses, respectively. The phase boundary as seen in Fig. 3 is exactly consistent with that for AHE previously reported.⁸

Figure 4 shows the magnetic field dependences of the magnetization, MCD and

Hall resistivity for Ti_{0.90}Co_{0.10}O_{2- δ} with (a) $n = 2 \times 10^{20}$ cm⁻³ and (b) $n = 4 \times 10^{21}$ cm⁻³ measured at room temperature. The applied magnetic field is perpendicular to the film plane for all the measurements. The curves coincide each other, expect for the non-essential deviation of the Hall resistivity in higher magnetic field due to the ordinary Hall effect. The magnetization, MCD, and Hall resistivity represent the ferromagnetic response of the static spins, photo-excited carriers, and itinerant charge carriers, respectively. Therefore, the coincidence of these measurements strongly suggests the presence of the single ferromagnetic source. Accordingly, we conclude that the ferromagnetism is not caused by insulating or optically inactive ferromagnetic precipitation. We also note that *x* is much below the percolation limit, hence, the magnetic Co cluster should not take significant role for the appearance of AHE.^{15,16} If we plot σ_{xx} and σ_{xy}^{AHE} values available in Ref. 14 and 15, the all date falls in the same trend in Fig. 4 in Ref. 8.

In conclusion, rutile $Ti_{1-x}Co_xO_{2-\delta}$ is shown to have ferromagnetic MCD for higher *n* and *x*. The good coincidence is demonstrated not only in the appearance of ferromagnetism in σ_{xx} -*x* space but also in the magnetic field dependences of MCD, magnetization, and AHE. These results represent that the ferromagnetism is originated from the single source: most probably the charge carriers induce the ferromagnetism.
