We report a general class of steady and transient states of granular gases. We might have the kinetic theory of inelastic gases admits stationary solutions with a power-law velocity distribution, f(v) v . The exponent is found analytically and depends on the spatial dimension, the degree of inelasticity, and the hom ogeneity degree of the collision rate. D riven steady-states, with the same power-law tail and a cut-o can be maintained by injecting energy at a large velocity scale, which then cascades to smaller velocities where it is dissipated. A sociated with these steady-states are freely cooling time-dependent states for which the cut-o decreases and the velocity distribution is self-sim ilar.

I. IN TRODUCTION

The statistical physics of granular gases is unusual in m any ways [1, 2, 3]. Shaking a box of beads, no m atter how hard, fails to generate a thermal distribution of energy. Instead, the velocity distributions are not M axwellian [4, 5, 6] and energy m ay be distributed unevenly in space [7, 8, 9] or am ong di erent components of a polydisperse granular media [10, 11]. M oreover, spatial correlations may spontaneously develop [12]. G ranular gases also exhibit interesting collective phenom ena such as shocks [13, 14], clustering [15, 16, 17, 18, 19], and hydrodynam ic instabilities [20, 21]. Energy dissipation, which results from inelastic collisions, is largely responsible for this rich phenom enology.

D ilute granular m atter can be studied system atically using kinetic theory. This approach has been used to quantitatively m odel situations where the dynam ics are prim arily collisional [22, 23, 24, 25]. K inetic theory has been used to derive transport coe cients in the continuum theory of rapid granular ow s, and it has also been used to m odel freely evolving and driven granular gases.

Spatially hom ogeneous system s are a natural starting point for investigations of granular gases. Theoretical, computational, and experimental studies show that the system cools inde nitely without energy injection, and that it reaches a steady-state when energy is injected to counter the dissipation. In the freely cooling case, the velocity distribution follows a self-similar form and in the forced case, the velocity distribution approaches a steady-state. In either case, the velocity distributions have sharp tails, and in particular, all of their moments are nite.

In this study, we consider the very same spatially ho-

m ogeneous granular gases and show that there is an additional fam ily of steady and transient states. First, we demonstrate that for a special, analytically soluble case, the unforced Boltzm ann equation admits nontrivial stationary states where the velocity distribution has a power-law high-energy tail. Then, we show that in general, the tail of the distribution obeys a linear equation and use this master equation to demonstrate that stationary states with power-law tails are generic, existing for arbitrary dimension and arbitrary collision rules. The characteristic exponents are obtained analytically [26].

The mechanism responsible for these stationary states is an energy cascade from large velocity scales to sm allvelocity scales that occurs due to the inelastic particle collisions. Driven steady-states with the same characteristic exponent and a high velocity cut-o can be maintained by injecting energy at a large velocity scale to compensate for the energy dissipated in the cascade. We com m these steady-states using M onte C arb simulations. We propose that such steady states can be experimentally realized in driven granular systems in which energy is injected at large velocities.

There is also a family of closely related freely cooling time-dependent states. We demonstrate this explicitly in one-dimension. In these transient states, the velocity distribution coincides with the stationary distribution up to some large velocity scale, but falls o exponentially beyond that scale. This cut-o velocity obeys Ha 's cooling law and decreases algebraically with time until the power-law range collapses. The velocity distribution is self-similar and the underlying scaling function is obtained analytically using the linear Boltzm ann equation. These freely cooling states are con im ed using numerical integration of the Boltzm ann equation.

This paper is organized as follows. The system is setup in section II and a special case is solved in section III. Dynamics of large velocities and the linear Boltzm ann equation are described in section IV. Stationary states are detailed in section V, driven steady-states in section

VI and transient states in section VII.We conclude in section VIII.

II. IN ELASTIC GASES

W e study a spatially hom ogeneous system of identical particles undergoing inelastic collisions. First, we consider one-dimension where the linear collision rule is

$$v_{1;2} = pu_{1;2} + qu_{2;1}$$
 (1)

with $v_{1;2}$ the post collision velocity and $u_{1;2}$ the precollision velocity. The collision parameters p and q obey p + q = 1. The relative velocity is reduced by the restitution coe cient r = 1 2p as follows: $(M_{1} \ V_{2}) =$ $r(u_{1} \ u_{2})$. In each collision, momentum is conserved, but the total kinetic energy decreases. The energy loss is $E = pq(u_{1} \ u_{2})^{2}$. Energy dissipation is maximal for the extreme case of completely inelastic collisions (r = 0; p = 1=2) and it vanishes for the extreme case of elastic collisions (r = 1; p = 0).

In this study, we consider the general collision rate

$$K (u_1; u_2) = j u_1 u_2 j$$
 (2)

with 0 1 the hom ogeneity index. For particles interacting via the central potential U (r) r , the homogeneity index is = 1 2^{d-1} [27, 28]. There are two limiting cases: (i) H ard-spheres, where the collision rate is linear in the velocity di erence, = 1, are used to m odel ordinary granular m edia; (ii) M axwell-m olecules, where the collision rate is independent of the velocity are used to m odel granular m edia with certain dipole interactions [29, 30, 31, 32, 33].

Let f(v;t) be the distribution of particles with velocity v at time t. It is normalized to unity, dvf(v) = 1 (henceforth the dependence on t is left implicit). For freely evolving and spatially hom ogeneous systems the distribution obeys the Boltzm ann equation

In this master equation, the kernel equals the collision rate (2) and the gain and loss terms simply relect the collision law (1). The Boltzmann equation assumes perfect mixing as the probability of inding two particles at the same position is taken as proportional to the product of the individual particle probabilities. It is exact when the strong condition of perfect mixing or \modecular chaos" is met, but it is only approximate when the particle positions are correlated.

One well-known solution of the this equation is the \hom ogeneous cooling state" where the velocity distribution is self-sim ilar in the long time lim it [34, 35],

$$f(v;t)' \frac{1}{v_0} = \frac{v}{v_0}$$
 (4)

with the characteristic velocity v_0 . Applying dimensional analysis, the collision rate K / v_0 should be inversely proportional to time, K t^1 . This leads to Ha \prime s cooling law [38]

$$v_0 t^{1=}$$
: (5)

A lternatively, it follows from the rate equation $dv_0 = dt / v_0^{1^+}$, in plying that exponential decay occurs for the limiting case of M axwell m olecules. Statistics of energetic particles are characterized by the tail of the distribution, and for freely cooling states, there is a stretched exponential decay [34, 36, 37]

for $> 0 \operatorname{as} \frac{1}{2} j! 1$.

In the freely cooling states, all energy is dissipated from the system and the particles come to rest, f (v;t) ! (v) as t ! 1. Thus, the system reaches a trivial stationary state. A re there any nontrivial stationary states? Quite supprisingly, the answer is yes. Our main result is that generically, there is a fam ily of nontrivial stationary solutions of the Boltzm ann equation.

III. AN EXACT SOLUTION

The stationary velocity distribution can be obtained analytically for one-dimensional Maxwell molecules. Since the governing equation (3) is in a convolution form, it is natural to employ the Fourier transform [39], $F(k) = dv e^{ikv} f(v)$. The stationary state (e=et=0) satis es the non-local and non-linear equation [40, 41]

$$F(k) = F(pk)F(qk)$$
: (7)

Normalization implies F(0) = 1.

For elastic collisions, p = 0, every distribution is a stationary state, but this is a one-dimensional anomaly, because in higher dimensions, the stationary distribution is always Maxwellian [29]. For all 0 p 1 and p+q=1, there is a family of stationary solutions

$$F(k) = \exp(v_0 \dot{x});$$
 (8)

characterized by the arbitrary typical velocity v_0 . Performing the inverse Fourier transform, the velocity distribution is a Lorentz (Cauchy) distribution [42]

$$f(v) = \frac{1}{v_0} \frac{1}{1 + (v = v_0)^2};$$
 (9)

This distribution decays algebraically at large velocities. For freely cooling M axwell-m olecules in one-dimension, the velocity distribution has a related form, a squared Lorentzian [43].

This stationary distribution does not evolve under the collision dynam ics since at each velocity there is perfect balance between collisional loss and collisional gain. The total energy density and the total dissipation rate are both divergent due to the shallow tail of the velocity distribution.

To analyze the general behavior, we focus on the dynam ics of very energetic particles. This allows us to derive the power-law decay and to obtain the characteristic exponent for all spatial dimensions and all collision param eters.

A. One-D im ension

The collision integral in Eq. (3) greatly simplies in the limit v ! 1. Since the distribution decays sharply at large velocities, the product $f(u_1)f(u_2)$ is maximal when one of the pre-collision velocities is large and the other small. For the gain term there are two possibilities: either u_1 u_2 and then $v = pu_1$ or u_2 u_1 and then $v = qu_2$. Let us denote the large velocity by u and the small one by w. The double integral separates into two independent integrals,

$$\frac{\text{@f(v)}}{\text{@t}} = \begin{array}{ccc} Z & Z \\ dw f(w) & du j_{1}j f(u) \\ [(v \quad pu) + (v \quad qu) & (u)]; \end{array}$$

Here, the collision rate ju wj was approximated by juj. The integral over the smaller velocity equals one, and performing the integration over the larger velocity yields

$$\frac{(lf(v))}{(lt)} = jvj \quad \frac{1}{p^{1+}}f \quad \frac{v}{p} + \frac{1}{q^{1+}}f \quad \frac{v}{q} \qquad f(v) : (11)$$

The tail of the velocity distribution satis es a non-local but linear evolution equation.

The linear Boltzm ann equation is valid for broader conditions compared with the full nonlinear Boltzm ann equation. The only requirement is that energetic particles are uncorrelated with slower particles. This is a weaker condition than the \stosszahlansatz" that the two particle density be equal to a product of one-particle densities.

Eq. (11) re ects that large velocities undergo the follow ing cascade process

$$v! (pv; qv);$$
 (12)

with the rate jvj. These cascade dynamics follow directly from the collision rule (1) by setting one of the incoming velocities to zero. Even though the number of particles is conserved, the number of energetic particles doubles in each cascade event (Fig. 1). Moreover, momentum is conserved but energy is dissipated in each cascade event: it is transferred from large velocities to smaller velocities.

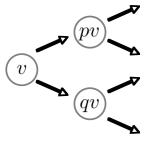

FIG.1: The cascade process.

In general dimensions, the collision rule is

$$v_1 = u_1$$
 (1 p) (u_1 u_2) fif: (13)

Here \hat{n} n=n with n \dot{n} j is a unit vector parallel to the in pact direction n (connecting the particle centers), $v_{1;2}$ are the post-collision velocities, and $u_{1;2}$ are the precollision velocities. The norm al (to \hat{n}) component of the relative velocity is reduced by the restitution coe cient r=1 2p as follows, $(v_1 \ v_2)$ $\hat{n}=r(u_1 \ u_2)$ \hat{n} and the energy dissipated equals $p(1 \ p)j(u_1 \ u_2)$ $\hat{n} \hat{f}$. Similarly, the general collision rate (2) becomes K $(u_1;u_2)=j(u_1 \ u_2)$ $\hat{n}j$. The velocity distribution $f_d(v)$ satis es

$$\frac{\theta}{\theta t} f_{d}(v) = d\hat{n} du_{1} du_{2} j(u_{1} \quad u_{2}) \quad \hat{n} j f_{d}(u_{1}) f_{d}(u_{2})$$

$$[(v \quad v) \quad (v \quad u)]: \quad (14)$$

In addition to integration over the incoming velocities, an additional integration over the impact direction is required, and this integration is normalized, $d\hat{n} = 1$. The impact angle is assumed to be uniform ly distributed.

The dynamics of large velocities v! 1 are simplied as in the one-dimensional case. The integration over the incoming velocities is separated into an integral over a small velocity and an integral over a large velocity u. The form er integration is immediate,

$$\frac{e}{et} f_{d}(v) = d\hat{n} du j_{u} \hat{n} j f_{d}(u)$$
(15)
[(v (1 p)u $\hat{n} \hat{n}$)+ (v u+(1 p)u $\hat{n} \hat{n}$)+ (v u)]:

Let = $(\hat{n} \ \hat{n})^2$; in other words, if is the angle between the dominant velocity and the impact angle, then = \cos^2 . There are two gain terms corresponding to the two cases $v = (1 \ p)u \ \hat{n} \ \hat{n}$ and $v = u \ (1 \ p)u \ \hat{n} \ \hat{n}$. These collision rules, together with the impact angle, dictate the magnitudes of the post-collision velocity in terms of the pre-collision velocity, v = u and v = u with the following stretching parameters

$$= (1 p)^{1=2};$$
 (16a)

$$= 1 (1 p^{2})^{1=2}$$
: (16b)

The parameter follows from $\hat{u} =$ nî and the parameter is obtained by introducing = v u and then employing the collision rule W w $\hat{n} = (1 \quad p)u \hat{n} = (1 \quad p)u^{1=2}$ and the idenw = tity $v^2 = u^2 + w^2$ 2uw ¹⁼². The integration over the large velocity u includes separate integrations over the velocity magnitude u and over the velocity direction û but since this angle is a unique function of the in pact angle, the latter integration is immediate. Using the isotropic velocity distribution $f_d(v)$ $S_{d}v^{d-1} f(v)$ with $S_d dv v^{d-1} f(v) = 1$ and S_d the area of the d-dim ensional unit hypersphere, Eq. (15) sim pli es to

$$v^{d-1} \frac{\partial f(v)}{\partial t} = dn du ju^{1=2} j u^{d-1} f(u)$$
 (17)

Finally, we simplify the angular integration, dri / sin^d $^2\,$ d . Denoting the angular integration with angular brackets hgi dri g (ri), we have

hgi = C d g()
$$^{1=2}$$
 (1) $^{\frac{d}{2}}$: (18)

The constant C = 1=B $(\frac{1}{2}; \frac{d}{2})$, with B (a;b) the beta function, is set by normalization. The linear equation governing the tail of the distribution is therefore

$$\frac{\partial f(v)}{\partial t} = v \quad \stackrel{=2}{=} \frac{1}{d+} f \quad \stackrel{v}{=} + \frac{1}{d+} f \quad \stackrel{v}{=} \quad f(v) :$$
(19)

A s in one-dimension, large velocities undergo the cascade process

but in general dimension, the stretching parameters acquire a dependence on the impact angle. In each collision, the total velocity m agnitude increases, despite the fact that the total energy decreases, as re ected by the following two inequalities

$$^{2} + ^{2}$$
 1: (21b)

E qualities occur in the limiting cases: the total velocity m agnitude is conserved in one dimension where collisions are always head-on (= 1) and, of course, the total energy is conserved for elastic collisions (p = 0). A ctually, a stronger statement than (21) holds: the quantity M_s(;) = ^s + ^s 1 is positive for s 1, negative for s 2, and it may be either positive or negative in the range 1 < s < 2, depending on the impact angle.

V. STATIONARY STATES

W e have seen that the velocity distribution decays algebraically for one-dimensional Maxwell molecules. The

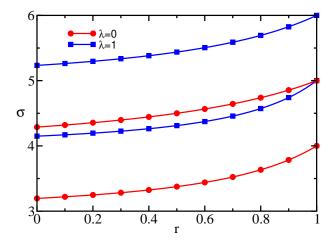

FIG.2: The exponent versus the restitution coe cient r for hard-spheres (=1) and M axwell m olecules (=0). The top two curves are for d = 3 and the bottom two curves are for d = 2.

linear equation for the tail of the distribution shows that this behavior extends to all and all p in one-dimension. The power-law velocity distribution

satis es the linear Boltzm ann equation (11) with the time derivative set to zero when $p^{-1} + q^{-1} = 1$. Since the collision parameters satisfy p + q = 1, the characteristic exponent in one-dimension is simply

$$= 2 + :$$
 (23)

Of course, the power-law behavior applies only for the tail of the distribution.

A lgebraic behavior holds in arbitrary dimension. Substituting Eq. (22) into the general linear Boltzm ann equation (19), the characteristic exponent is root of the equation

D

d
 + d 1 $^{=2}$ = 0: (24)

This transcendental equation can be re-written explicitly in terms of the gamma function and the hypergeometric function [44]

$$\frac{1}{(1 \ p)^{d}} \frac{2F_1}{(1 \ p)^{d}} = \frac{(\frac{d+1}{2}) (\frac{d+1}{2})}{(\frac{d+1}{2})^{d}} : (25)$$

The exponent (d; ;r) varies continuously with the spatial dimension d, the hom ogeneity index , and the restitution \cos cient r (gure 2).

According to the bounds (21) the left hand side of Eq. (24) is positive when d 1 but negative when d 2. Therefore, this quantity changes sign when 1 d 2 leading to the relatively tight bounds

$$d + 1 + d + 2 + :$$
 (26)

The lower bound (23) is realized in one-dimension where the collisions are alw ays head-on, while the upper bound is approached, ! d + 2 + , in the quasi-elastic lim it r! 1. We note that the two limiting cases of onedim ension and elastic collisions do not commute. Moreover, the zero dissipation lim it is singular: M axwellian distributions occur when the collisions are elastic [29].

Since the energy lost in each collision is proportional to $(v)^2$ and the collision rate is proportional to j v j, the energy dissipation rate is related to the following integral, h^{2^+} i where hq (v)i $S_d dv v^{d-1} f(v)g(v)$. d + 2 + Hence, the bound im plies that the total dissipation rate is divergent. This is a generic feature of the stationary solutions, and in fact it shows why Ha 's $\operatorname{cooling} \operatorname{law} dT = dt =$, where $T = h \forall i$ is the granular tem perature, does not apply: this rate equation assum es

nite dissipation rates. In contrast, the total energy may be either nite or in nite because both > d + 2 and

< d+ 2 are possible. The stationary states studied here appear to be fundam entally di erent than the in nite energy solutions of the elastic Boltzm ann equation because they require dissipation and because they always involve in nite dissipation [45].

The characteristic exponent increases monotonically with the spatial dimension, the hom ogeneity index, and the restitution coe cient. Thus, xing d and , the com pletely inelastic case (r = 0) provides a lower bound for with respect to r (gure 2). For hard-spheres the completely inelastic limit yields = 4:1922 and 523365 in two-and three-dimensions, while for Maxwell m olecules the corresponding values are = 3:19520 and

= 428807.

The power-law behavior is in sharp contrast with the stretched exponential tails f (v) exp(jvj) that typically characterize granular gases. For freely cooling gases, as in (6), and for therm ally forced gases, = 1 + = 2[46, 47, 48, 49]. Both behaviors im mediately follow from the linear Boltzm ann equation (19); in the forced case, the time derivative in (19) is replaced by the di usive forcing term @=@t! Dr². Only in the lim iting case of freely cooling M axwell m olecules do power-law velocity distributions arise, but the solutions are not stationary and the characteristic exponent di ers from the stationary solutions [50, 51, 52, 53].

VI. DRIVEN STEADY-STATES

In this section we describe driven, non-equilibrium steady-states that are identical, except for a high velocity cut-o , to the stationary states described above. In these steady-states energy is injected at a large velocity scale, cascades to sm all velocities, and is dissipated over a broad power-law range. The energy in jection scale V must be well separated from the typical velocity scale v_0 , but otherwise, the injection mechanism is not unique. W e study several concrete cases where energy is in jected with a sm all rate at a large velocity.

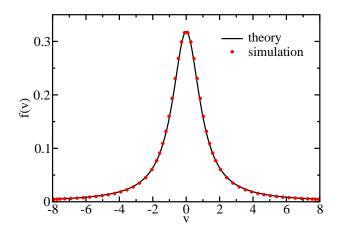

FIG. 3: The velocity distribution for one-dimensional Maxwell molecules. The solid line is a Lorentzian and the typical velocity is $v_0 = 0.055$.

As we have seen in the exactly soluble case of onedimensional Maxwell molecules, there is a family of steady-state solutions characterized by the typical velocity v_0 : if f (v) is a steady-state solution, so is v_0^d f (v=v_0) for arbitrary v₀. Let the energy in jection rate (per particle) be and let the injection velocity be V. This scale sets an upper cuto on the velocity distribution, beyond which the distribution should rapidly vanish. Since the system is at a steady-state, the dissipation rate

$$\begin{array}{cccc} & & & & & & \\ & h \hat{v}^{+} & i & & dv v^{d+1+} & v_{0}^{d} f (v=v_{0}) & (27) \\ & & & & \\ & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ & & & & & \\ \end{array}$$

must be balanced by the energy in jection rate V^2 , leading to a general relation between the injection rate, the in jection velocity and the typical velocity,

$$V (V = v_0)^d$$
 : (28)

To verify the theoretical predictions, we perform ed M onte Carlo simulations. Collisions are simulated by selecting two particles at random with a probability proportional to the collision rate and then updating their velocities according to the collision rule (13). Energy is injected with a small rate using the following \lottery" in plementation. An energy loss counter keeps track of the cumulative energy loss. With a small rate, a random ly chosen particle is \awarded" an energy equal to the reading on the loss counter. Subsequently, the loss counter is reset to zero. W ith this protocol, the kinetic energy remains practically constant, and moreover, energy injection occurs only at large velocity scales. For one-dimensional hard-spheres, we tested a di erent in jection mechanism. The injection energy was drawn from a Maxwell-Boltzmann distribution with a very large energy. W ith a small rate, this energy was added to a random ly chosen particle.

W e simulated completely inelastic M axwell m olecules and hard spheres in one- and two-dimensions starting

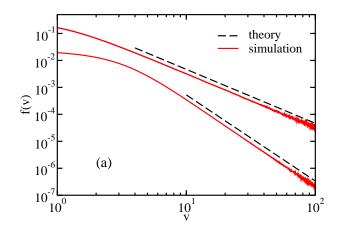

FIG. 4: The velocity distribution for M axwell m olecules. The top curves correspond to one-dimension and the bottom curves to two-dimensions.

with a uniform velocity distribution with support in the range [1:1]. A fler a short transient, the system reaches a steady-state. For the special case of one-dimensional M axwell molecules, we veri ed that the velocity distribution is Lorentzian (gure 3). In all cases, the tail of the velocity distribution decays as a power-law, and the exponent is in excellent agreement with the theoretical prediction, Eq. (25). M axwell molecule simulation results are displayed in gure 4 and hard sphere simulation results in gure 5.

The energy balance relation (28), combined with the constant energy condition hv^2i 1, im posed in our simulations, yields an estimate for the typical velocity. Dierent behaviors emerge for nite energy and in nite energy distributions.

W hen < d+2, the constant energy constraint in plies $V^{d+2} = v_0^d$, that combined with energy balance (28) reveals how the maxim alvelocity and the typical velocity scale with the injection rate

$$V = \frac{1}{2};$$
 (29a)

$$v_0 = \frac{d+2}{(-d)(2-)}$$
: (29b)

Simulations with d = 1, = 0, and $= 10^4$, are characterized by V 10^2 and $v_0 = 10^2$, consistent with these scaling laws.

In the complementary case, > d + 2, the typical velocity v_0 1 is set by the initial conditions because hv^2i v_0^2 . Energy balance (28) yields

V
$$\frac{1}{d}$$
: (30)

Simulations with d = 2, = 1, and $= 10^{2}$ should be characterized by the injection scale V 50, as in this case = 4.15. The data is consistent with this estimate.

As long as the system is su ciently large, there is no dependence on the system size (the number of particles). The total energy and the total dissipation rate are proportional to the system size, and in general, all therm odynam ic properties are extensive.

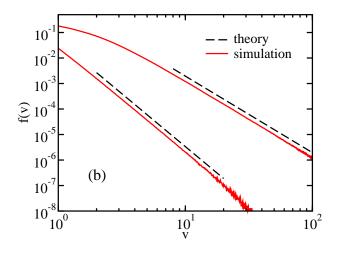

FIG. 5: The velocity distribution for hard spheres in one-dimension (top curves) and in two-dimensions (bottom curves).

Based on the theoretical and the simulation results, we conclude that there may be qualitative di erences between the nite energy and in nite energy cases, but that fundam entally, the steady-state solutions are of one nature. They represent a nonequilibrium stationary-state where energy is injected at velocity scale V and dissipated at velocity scale v_0 . These scales are set by the injection rate and the injection protocol.

VII. TIM E-DEPENDENT STATES

W hat happens to these steady states when energy injection is turned-o? Steady-state solutions of the type (22) can be realized only up to some upper cuto . Such truncated power-law distributions are still com pact, and thus, in the absence of energy input, they should undergo free cooling with all energy eventually dissipated from the system.

Therefore, we anticipate that there is a time-dependent velocity cut-o V (t). Below this scale the distribution is nearly the same as the stationary distribution but above this scale, the distribution has a sharp tail, analogous to the freely cooling state (4). Thus, the distribution is of the form f (v;t) f(v; V) such that for v < V(t), $f_{\!s}\left(\!v\right)$ while for $\!v$ > V (t), the distribution def(v;V) cays faster than a power law . Here $f_s(v)$ is the stationary solution of the full Boltzm ann equation. W e assume that the cut-o scale is much larger than the typical veloc v_0 and, without loss of generality, set v_0 ity, V 1. The assumption that the distribution is unmodi ed below the cut-o velocity is consistent with the character of the energy cascade. Furtherm ore, we expect that the functional form of the cut-o depends only on the scaled variable, v=V.

F irst, consider the time dependence of the cut-o scale V (t). G iven the assumption that cooling occurs only

through a decrease in the cut-o scale, the rate of change of the energy is

$$\frac{dE}{dt} = \frac{dhv^{2}i}{dt} = \frac{d}{dt}^{Z_{v(t)}} dv v^{d+1} f_{s}(v) \quad (31)$$
$$V^{d+1} \quad \frac{dV}{dt}:$$

The decrease in energy equals the dissipation rate V $^{d+2+}$ from Eq. (27), showing that the cut-o velocity obeys Ha 's cooling law,

$$\frac{\mathrm{d}V}{\mathrm{d}t} = \mathrm{d}V^{1+} : \qquad (32)$$

Therefore, the cut-o velocity decays with time as follows

$$V (t) = \frac{V (0)}{1 + c V (0)t}$$
(33)

where V(0) is the initial value of the cut-o .

Restricting our attention to one-dimension we seek similarity solutions of the type

$$f(v;t)' f_{s}(v) \frac{v}{v}$$
: (34)

Here, $f_s(v)$ is the stationary solution of Eq. (3) that decays as a power-law at large velocities $f_s(v)$ ' Av². The cut-o function approaches unity at small arguments, (x) ! 1 as x ! 0 so that the stationary solution is recovered for v V.

Substituting the time dependent form (34) into the linear governing equation (11) yields

$$\frac{dV = dt}{V^{1+}} {}^{0}(x) = x^{-1} p \frac{x}{p} + q \frac{x}{q} \qquad (x) :$$
(35)

A sum ing the cut-o velocity satis es Eq. (32) with constant of proportionality c, the scaling function satis es the linear and non-local di erential equation

$$c^{0}(x) = x^{1} p \frac{x}{p} + q \frac{x}{q}$$
 (x); (36)

with the boundary conditions (0) = 1 and (x) ! 0 as x ! 1 . N ote that (x) must be non-analytic at x = 0 because all its derivatives vanish at x = 0 since p + q = 1 and (0) = 1.

For large arguments, the last term on the right hand side dom inates, and therefore, the tail of the distribution is a stretched exponential as in (6)

with $C = (c)^{1}$ for > 0. In the limiting case = 0all terms on the left-hand side are comparable and the tail is algebraic: (x) x with c = 1 p⁺¹ q⁺¹. Thus, both the decay of the cut-o velocity and the tail behavior are as for ordinary freely cooling solutions, Eq. (4). There is, however, a di erence since the distributions considered here have two characteristic velocities, V and v_0 and it is only the upper cut-o , V that evolves in time. A fler V and v_0 become comparable, the behavior crosses over to the hom ogeneous cooling state [34, 35] with a single characteristic velocity, v_0 .

We now focus on completely inelastic hard-spheres (= 1 and p = q = 1=2) for which an exact solution is possible. Integrating Eq. (36) and in posing (0) = 1 gives c = (1 $p^2 - q^2)_0^{-1} dx$ (x), but since the cut-o scale V is dependent up to a constant, we may set the integral value, $_0^{-1} dx$ (x) = 1 leading to c = 1 $p^2 - q^2$. When p = q = 1=2 then c = 1=2 and Eq. (36) becomes

$$f^{(x)}(x) = 2 [(2x) (x)]:$$
 (38)

This equation can be solved using the Laplace transform $h(s) = dx e^{sx}$ (x), that satis es the non-local equation

$$(2 + s)h(s) = 1 + h(s=2)$$
 (39)

with the boundary condition h(0) = 1 set by the normalization. Since (x) ! 1 as x ! 0 then $h(s) ! s^{1}$ as s ! 1, so we make the transform ation $h(s) = s^{1} [1 \quad g(s)]$ with g(0) = 1 and $g^{0}(0) = 1$. The auxiliary function g(s) satis are recursion-like equation $g(s) = (1 + s = 2)^{1} g(s = 2)$. Solving iteratively and invoking g(0) = 1, the solution is the in nite product $g(s) = \prod_{n=1}^{1} (1 + s = 2^{n})^{1}$, and the Laplace transform is

h (s) =
$$\frac{1}{s}$$
 1 $\frac{\dot{Y}}{1}$ $\frac{1}{1 + \frac{s}{2^n}}$: (40)

Since the in nite product has a series of simple poles at $s = 2^n$ for every integer n 1, the scaling function is a sum of exponentials

$$x^{2}$$

(x) = $a_{n} \exp(2^{n}x)$ (41a)
 $a_{n=1}$

$$a_{n} = \frac{Y}{\sum_{\substack{k=1\\k \in n}}^{k=1} \frac{1}{1 - 2^{n-k}}};$$
 (41b)

with the coe cients obtained as the residues to the poles $a_n = \lim_{s! 2^n} [(s + 2^n)h(s)]$. In contrast with freely cooling states (4), the scaling function (x) can be obtained exactly.

The Laplace transform conveniently yields the limiting behaviors of the scaling function. The simple pole closest to the origin relevant to the tail behavior

(x) '
$$a_1 \exp(2x)$$
 (42)

as x ! 1 with $a_1 = 3.46275$ obtained from Eq. (41b). M ore interesting is the small x behavior, released by the large s behavior

$$Z_{1}$$

dx [1 (x)] e^{sx} = s¹ g(s) ! s¹ exp C (ln s)²

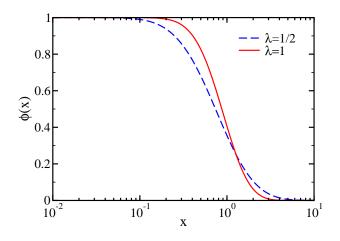

FIG. 6: The scaling function (x) versus x for = 1=2 (dashed line) and = 1 (solid line).

as s ! 1 with $C = (2 \ln 2)^{1}$. The function g(s) was estimated by replacing the in nite product with a nite product

$$\frac{\dot{Y}}{1+\frac{s}{2^{n}}} = \frac{Y}{1+\frac{s}{2^{n}}} = \frac{2^{n}}{s} ! \exp (C (\ln s)^{2})$$
(43)

with $n = \ln_2 s$. Inverting the log-norm all aplace transform using the steepest descent m ethod, the leading correction to the scaling function is log-norm alas well

"
$$2^{\#}$$

1 (x) exp A ln $\frac{1}{x}^{2}$; (44)

as x ! 0 with $A = C = 4 = (8 \ln 2)^{1}$. Thus, the scaling function is perfectly at near the origin as all its derivatives vanish at x = 0 (gure 6). Physically, the small x behavior shows that there is a sizable range of velocities for which the time-dependent velocity distribution (34) coincides with the steady-state solution, f (v;t) ' f_s (v).

The series solution (41) can be straightforwardly generalized to all > 0

$$(x) = \sum_{n=1}^{X^{2}} a_{n} \exp((2^{n}x));$$
 (45a)

$$a_{n} = \frac{Y}{\sum_{\substack{k=1\\k \in n}}^{k=1}} \frac{1}{1 - 2^{(n-k)}} :$$
(45b)

Making the transformation y х and setting 12 the proportionality constant c =such that c = 1 dy (y), Eq. (38) is generalized, 2 0 $^{0}(y) = 2$ (y). Consequently, the Laplace (2 y) transform is obtained from Eq. (40) by replacing 2^n with 2^{n} , and repeating the steps leading to (41) gives (45). Figure 6 shows the scaling function for = 1=2. As decreases the cut-o becom es less sharp and the at region near x = 0 less broad.

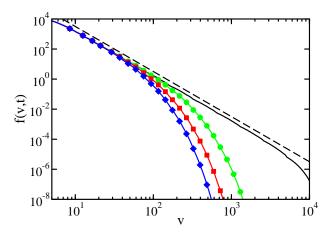

FIG.7: The velocity distribution f (v;t) versus v. Shown is the steady-state distribution before the injection is turnedo (solid line) and at three consecutive and equally-spaced later times (circles, squares, diamonds) during free cooling. A lso shown for reference is a dashed line with slope -3. The velocity is in arbitrary units.

In summary, we nd that there are time-dependent states associated with the stationary states. In these transient states, the velocity distribution is characterized by a cut-o velocity scale that decays with time according to Ha 's law. Below this velocity, the energy cascade is una ected and the velocity distribution agrees with the stationary distribution but above this scale, the distribution is exponentially suppressed. We relied only on the linear Boltzm ann equation to derive a scaling form for the cut-o function. Of course, the full nonlinear equation (3) is still relevant as it governs the dynam - ics of sm all velocities via the stationary solution f_s (v). This guarantees that the velocity distribution is properly norm alized, and speci cally, that the integral over sm all velocities remains nite.

W e num erically integrated the hard-sphere Boltzm ann equation in one-dimension to verify these predictions. Velocity bins are kept, each with a double precision num – ber representing the number of particles within that velocity range. In the simulation, two velocity bins are chosen random ly with a rate proportional to the collision rate. W hen two bins \collide", particles are transferred from each into target bins, determined by the collision rule (1).

We generated the stationary distribution by injecting energy at a xed rate. This was done by uniform ly rem oving particles from the distribution and re-injecting them according to a Gaussian distribution with a large characteristic velocity. Once the system reaches the stationary state, we turn o the energy injection and observe the distribution f (v;t) as it cools.

Figure 7 shows the driven steady-state distribution and the freely cooling distributions at three later times. The results verify that the steady-state has a power-law tail, $f_s(v) = v^3$ and that the freely cooling distributions are close to the steady-state distribution for su ciently

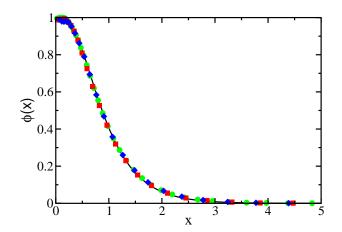

FIG.8: The scaling function underlying the velocity distribution. The velocity distributions in gure 7 were normalized by the stationary distribution as in Eq. (34). The solid line is the theoretical scaling function (41).

sm all velocities. Figure 8 shows the same three timedependent distributions divided by the steady distribution as in Eq. (34) and rescaled by the cut-o velocity V (t) to collapse the data onto the theoretical prediction (41).

The time dependence of the cut-o velocity, given by Eq. (32), holds until V is order v_0 1. Thus, the lifetime of the collapsing power-law solution approaches a constant of order unity as V (0) becomes in nite. During most of the time that the power-law is collapsing, V decays algebraically with time, V (t) $t^{1=}$. Figure 9 shows the cut-o velocity versus time together with a t to the form (33) with = 1. We also checked that the tail of the cooling distribution is exponential. We conclude that for completely inelastic hard-spheres, the simulation results are in excellent agreement with the theoretical predictions.

VIII. CONCLUSIONS

In summary, we nd a new class of steady-state and time-dependent states for inelastic gases. In the nonequilibrium steady-states, energy is injected at large velocities, it cascades down to small velocities, and it is dissipated over a power-law range. Generically, the steadystate distributions have a power-law high-energy tail. The characteristic exponents were obtained analytically and they vary with the spatial dimension and the collision rules. Form ally, the stationary solutions are characterized by an in nite dissipation rate, while the energy density may be either nite or in nite. In an actual particle system, these steady-states may be realized only up to the energy injection scale, so that all therm odynam ic characteristics including the dissipation rate and the energy density are nite.

W hen injection is turned-o , the velocity distribution

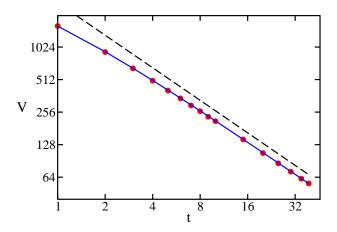

FIG.9: The cut-o velocity V (t) as a function of timet (circles). The solid line is a t to Eq. (33). Also shown is a broken line with slope 1.

is stationary only in a shrinking range of velocities and it decays sharply as a stretched exponential at large velocities. For completely inelastic collisions, the scaling function underlying this behavior can be obtained exactly from the linearized Boltzm ann equation and at sm all velocities, there is a subtle log-norm al correction to the power-law behavior. A lthough we analyzed only the onedim ensional case, we expect the same behavior in higherdim ension. These tim e-dependent states can be loosely thought of as a hybrid between a steady-state solution and the well-known, freely-cooling solution. Both the tim e-dependence of the characteristic velocity and the decay at large velocities are sim ilar, but not identical, to those occurring for freely cooling granular gases. A fter the cut-o velocity becom es com parable to the typical velocity, the velocity distribution presum ably crosses over to the freely cooling solutions.

C ascade processes occur in m any other physical system s. M athem atically, the inelastic cascade process for one-dimensional hard-spheres is identical to that found for the grinding process in Ref. [54], and in both problem s = 3. Indeed, the cascade process (12) is equivalent to a fragmentation process. In uid turbulence, the uid is forced at a large spatial scale, energy cascades from large scales to sm all scales, where it is dissipated due to viscosity [55]. A ctually, the situation found here for granular gases is analogous to wave turbulence, that is described by a kinetic theory for wave collisions [56]. O ne di erence with the K olm ogorov spectra of uid turbulence is that the characteristic exponents are irrational because they do not follow from dimensional analysis.

Inelastic cascades are a direct consequence of the collision rule and they are described by a linear equation. This equation should be valid under very broad conditions and it can be generalized to nonuniform distributions of in pact angles and collision parameters as well as polydisperse granular media. A dditionally, the cascade dynamics should extend to viscoelastic collision rules because the restitution coe cient depends only weakly on the relative velocity for energetic collisions [1].

The most signi cant condition for these steady-states concerns the driving mechanism : the injection rate must be small compared to the collision rate and the injection energy large compared to the typical energy. We propose that stationary distributions may be achieved in driven granular gas experiments where energy is injected at very large velocity scales. A lgebraic tails with exponents comparable with these reported here were observed recently in sheared granular layers, but these experiments involved frictional, rather than collisional, dynam ics [57].

Inelastic cascades should also arise when an energetic particle hits a static medium of inelastic particles, or alternatively, a background of slow ly moving particles. Indeed, the collision dynamics in this case reduce to the inelastic cascade discussed in this paper. This setup may be interesting to study theoretically and experimentally. In closing, the kinetic theory of inelastic collisions is rem arkable as the nonlinear Boltzm ann equation adm its a number of distinct solutions including steady-states, transient states, and hybrid states that interpolate between the two. Nonlinearity, nonlocality, and the lack of energy conservation are responsible for this rem arkable com plexity. We end with an open question: do other fam ilies of solutions exist?
