(D ated: M arch 23, 2024)

The cluster size dependence of superconductivity in the conventional two-dimensional H ubbard m odel, commonly believed to describe high-temperature superconductors, is system atically studied using the D ynam icalC luster A pproximation and Q uantum M onte C arlo simulations as cluster solver. D ue to the non-locality of the d-wave superconducting order parameter, the results on small clusters show large size and geometry elects. In large enough clusters, the results are independent of the cluster size and display a nite temperature instability to d-wave superconductivity.

Despite years of active research, the understanding of pairing in the high-tem perature \cuprate" superconductors (HTSC) remains one of the most important outstanding problems in condensed matter physics. W hile conventional superconductors are well described by the BCS theory, the pairing mechanism in HTSC is believed to be of entirely di erent nature. Strong electronic correlations play a crucial role in HTSC, not only for superconductivity but also for their unusual norm al state behavior. Hence, models describing it inerant correlated electrons, in particular the two-dimensional (2D) Hubbard model and its strong-coupling limit, the 2D t-J model, were proposed to capture the essential physics of the CuO-planes in HTSC [1, 2]. Despite the fact that these models are among the mostly studied models in condensed m atter physics, the question of whether they contain enough ingredients to describe HTSC remains an unsolved problem.

M any di erent techniques, from analytic to num erical have been applied to study superconductivity in these models. The Merm in -W agner theorem [3] and the rigorous results in Ref. [4] preclude dx2 y2 superconducting long-range order at nite temperatures in the 2D models. Superconductivity may however exist { as in the attractive Hubbard model { as topological order at nite tem peratures below the Kosterlitz-Thouless (KT) transition tem perature [5]. Recent renorm alization group studies indicate that the ground-state of the doped weakcoupling 2D Hubbard model is superconducting with a $d_{x^2 v^2}$ -wave order parameter [6]. The possibility of $d_{x^2 v^2}$ -wave pairing in the 2D Hubbard and t-J models was also indicated in a number of num erical studies of nite system size (for a review see [7]). Only recent num erical calculations for the t-J m odel provided evidence for pairing at T = 0 in relatively large system s for physically relevant values of J=t [8]. Q uantum M onte C arlo (Q M C) simulations are also employed to search for such a transition [9]. These studies indicate an enhancem ent of the pairing correlations in the $d_{x^2 y^2}$ channel with decreasing tem perature. Unfortunately the Ferm ion sign problem lim its these studies to tem peratures too high to study a possible KT transition. Another di culty of these m ethods arises from their strong nite size e ects, offen ruling out the reliable extraction of low -energy scales. In fact, a reliable nite-size scaling has only recently been achieved in the negative-U m odel [10], where the relevant tem perature scales are m uch higher. The available results for the positive-U m odel so far have thus been inconclusive, and a treatm ent within a non-perturbative schem e that goes beyond the conventional nite size techniques is clearly necessary to resolve the controversy as to whether there exists nite tem perature superconductivity in these m odels.

In this Letter we use the D ynam ical C luster A pproxim ation (DCA) [11] (for a review see [12]) to explore the superconducting instability in the 2D H ubbard m odel

$$H = t C_{i}^{y} c_{j} + U n_{i''} n_{i\#};$$
(1)
hiji; i

where $c_i^{(y)}$ (creates) destroys an electron with spin on site i, n_i is the corresponding number operator, t the hopping am plitude between nearest neighbors h:::i and U the on-site C oulomb repulsion. In the DCA we take advantage of the short length-scale of spin correlations in optim ally doped HTSC [13] to map the original lattice m odelonto a periodic cluster of size $N_c = L_c - L_c$ embedded in a self-consistent host. T hus, correlations up to a range $< L_c$ are treated accurately, while the physics on longer length-scales is described at the m ean- eld level. By increasing the cluster size, it thus allow s us to system atically interpolate between the single-site dynam ical m ean- eld result and the exact result while remaining in the therm odynam ic lim it. We solve the cluster problem using QMC simulations[14].

W e present results of large cluster calculations { up to 26 sites { that indicate that the 2D H ubbard m odel has a superconducting instability at a nite tem perature. This conclusion is reached due to several factors: Sim ulations on sm all clusters, where d-w ave order is topologically allowed, show large nite size and geom etry e ects leading to inconclusive results. How ever, since the average sign in DCA QMC simulations is signi cantly larger than in nite-size QMC counterparts, exploring low er tem peratures and larger clusters becomes possible. In addition, the advent of new parallel vector machines, such as the CRAY X1 at ORNL, improves the speed of these calculations by more than one order of magnitude compared to conventional architectures, making simulations on large clusters with a small average sign feasible. W ithin the limits of current computational capability, we observe nite transition temperatures in the largest a ordable clusters. There the results are independent of cluster size within the error bars, although we cannot preclude a further small reduction in transition temperatures in yet larger clusters.

Previous DCA simulations with a cluster of four sites, the smallest cluster that can capture $d_{x^2 v^2}$ wave pairing, with U equal to the bandwidth W = 8t, show good general agreem ent with HTSC [15]. In the param agnetic state, the low -energy spin excitations become suppressed below the crossover tem perature T , and a pseudogap opens in the density of states at the chem ical potential. At lower tem peratures, we nd a nite tem perature transition to antiferrom agnetic long-range order at low doping, while at larger doping, the system displays an instability to $d_{x^2 v^2}$ wave superconducting long-range order. This apparent violation of the M erm in-W agner theorem is a consequence of the small cluster size studied (see also [16]). M ore recent results obtained with a sim ilar quantum cluster algorithm con m the presence of antiferromagnetism and superconductivity in the groundstate of the 2D Hubbard model [17].

W ith increasing cluster size how ever, the DCA progressively includes longer-ranged uctuations while retaining som e m ean-eld character. Larger clusters are thus expected to system atically drive the N eel tem perature to zero and hence recover the M erm in-W agner theorem in the in nite cluster size lim it. In contrast, superconductivity m ay persist as K T order even for large cluster sizes.

Since the large cluster simulations presented here are at the limit of current computational capabilities, we are restricted in our ability to explore both the parameter space and dienent cluster sizes. We choose the parameters to favor superconducting and antiferrom agnetic order. In our study of superconductivity, we choose U = 4t = W = 2(we take t as our unit of energy). While we observe that larger values of U yield higher transition temperatures in the 4-site cluster, the smaller value of U greatly reduces the sign problem and thus allows us to simulate larger cluster sizes. We focus on a doping of 10%, where the pairing correlations are maximal for U = W = 2. To study antiferrom agnetism, we focus on the undoped model and set U = 8t, where the N eel tem perature is highest.

Furtherm ore, we have to be careful in selecting di erent cluster sizes and geom etries. M uch can be learned from simulations of nite size systems, where periodic boundary conditions are typically used. Betts and F lynn [18] system atically studied the 2D H eisenberg m odel on nite size clusters and developed a grading scheme to determ ine which clusters should be used. The main qualication is the \imperfection" of the near-neighbor shells: a measure of the (in)completeness of each neighbor shell compared to the in nite lattice. In nite size scaling calculations they found that the results for the most perfect clusters fall on a scaling curve, while the imperfect clusters generally produce results o the curve. Here, we employ some of the cluster geom etries proposed by Betts (see Fig. 1) to study the antiferrom agnetic transition at half lling and generalize Betts' argum ents to generate a set of clusters appropriate to study d-wave superconductivity.

To illustrate that the DCA recovers the correct result as the cluster size increases, we plot in Fig.2 the DCA results for the N eel tem perature $T_{\rm N}$ at half-lling as a function of the cluster size N $_{\rm c}$. $T_{\rm N}$ decreases slow by with increasing cluster size N $_{\rm c}$. As spin-correlations develop exponentially with decreasing tem perature in 2D, the N $_{\rm c}$ > 4 data falls logarithm ically with N $_{\rm c}$, consistent with $T_{\rm N}$ = 0 in the in nite size cluster limit. Thus, the M erm in-W agner theorem is recovered for N $_{\rm c}$! 1. The clusters with N $_{\rm c}$ = 2 and N $_{\rm c}$ = 4 are special because their coordination number is reduced from four. For N $_{\rm c}$ = 2 the coordination number is one and hence a local singlet is form ed on the cluster for tem peratures

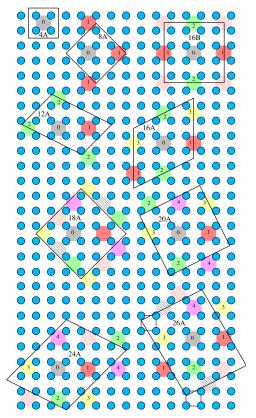

FIG. 1: Cluster sizes and geometries used in our study. The shaded squares represent independent d-wave plaquettes within the clusters. In small clusters, the number of neighboring d-wave plaquettes z_d listed in table I is smaller than four, i.e. than that of the in nite lattice.

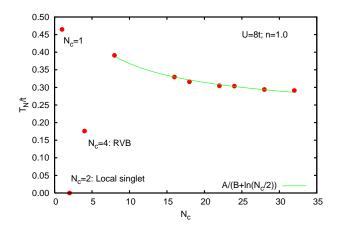

FIG.2: Neel temperature at half-lling when U = 8t versus the cluster size. $T_{\rm N}$ scales to zero in the in nite cluster size limit. The solid line represents a t to the function A=(B + ln(N_{\rm c}=2)) obtained from the scaling ansatz ($T_{\rm N}$) = L_c. For N_c = 2 a local singlet and for N_c = 4 the RVB state suppress antiferrom agnetism .

below J $t^2=U$. In the N_c = 4 site cluster, the coordination is two, so uctuations of the order parameter are overestimated and the resonating valence bond state [1] is stabilized. Hence, antiferrom agnetism is suppressed in these cluster sizes and their corresponding T_N does not fall on the curve.

We now turn to the main focus of this Letter, i.e. the search for a possible KT instability to the superconducting state. To check that the DCA form alism is able to describe such a transition, we rst tested the DCA-QMC code on the negative U, i.e. attractive Hubbard model which is known to exhibit a KT instability to an s-wave superconducting state [10]. We nd that the DCA indeed produces a nite tem perature s-wave instability to the KT superconducting state. Due to the local nature of the s-w ave order parameter, the DCA results converge rather quickly with cluster size. The DCA values for T_c agree with those recently obtained in nite size QMC simulations [10]. In addition, we checked that our DCA-QMC code reproduces the results of other DMFT codes when $N_c = 1$, and those of nite size QMC codes when the coupling to the self-consistent host is turned o .

To identify a possible KT transition in the positive U H ubbard model we calculate the $d_{x^2 \ y^2}$ -wave pair-eld susceptibility P_d for the clusters $N_c = 4A$, 8A, 16A, 16B, 18A, 20A, 24A and 26A. In contrast to the swave order parameter in the attractive model, the d-wave order parameter is non-local and involves four bonds or sites. Thus, large size and geometry elects have to be expected in small clusters. Similar to the cluster grading scheme B etts developed for magnetic order, we can classify the dilement clusters according to their quality for d-wave order. At low temperatures, local d-wave pairs will form, but phase uctuations of the pair wave-function prevent

the system from becoming superconducting. Since the DCA cluster has periodic boundary conditions, each foursite d-wave plaquette has four neighboring d-wave plaquettes. However, as illustrated in Fig. 1, in small clusters, these are not necessarily independent and the e ective dimensionality may be reduced.

Fig. 1 shows the arrangement of independent d-wave plaquettes in the clusters used in our study and their corresponding number z_d is listed in table I. In the in nite system , z_d = 4. The N $_c$ = 4 cluster encloses exactly one d-wave plaquette ($z_d = 0$). W hen a local d-wave pair form s on the cluster, the system becom es superconducting, since no superconducting phase uctuations are included. Thus, the N_c = 4 result corresponds to the mean-eld solution. In the 8A cluster, there is room for one more d-wave pair, thus the number of independent neighboring d-wave plaquettes $z_d = 1$. Since this same neighboring plaquette is adjacent to its partner on four sides, phase uctuations are replicated and hence overestim ated as compared to the in nite system. The situation is sim ilar in the 16B cluster, where only two independent (and one next-nearest neighbor) d-wave plaquettes are found $(z_d = 2)$. In contrast, $z_d = 3$ in the oblique 16A cluster. We thus expect d-wave pairing correlations to be suppressed in the 16B cluster as com pared to those in the 16A cluster. W ith the exception of the 18A cluster, where neighboring d-wave plaquettes share one site and thus are not independent, the larger clusters 20A, 24A, and 26A all have $z_d = 4$ and are thus expected to show the most accurate results. Hence, as the number of independent neighboring d-wave plaquettes, zd, is reduced from four, phase uctuations are replicated due to periodic boundary conditions and thus overem phasized, suppressing pairing correlations and consequently ${\tt T}_{\tt c}$. Note that the e ects of nite size energy levels on the pairing correlations were pointed out in QMC simulations of Hubbard ladders [19].

TABLE I: Number of independent neighboring d-wave plaquettes z_d and the values of $T_c^{K\,T}$ and $T_c^{\rm lin}$ obtained from the K osterlitz-Thouless and linear ts of the pair-eld susceptibility in Fig. 3, respectively.

Fig.3 shows the tem perature dependence of the inverse d-wave pair- eld susceptibility, $1=P_d$, in the 10% doped system. Since a proper error propagation is severely ham - pered by storage requirem ents, we obtain the error-bars shown on the 16A results from a number of independent runs initialized with di erent random number seeds. E mor-bars on larger cluster results are expected to be of the sam e order or larger. The results clearly substantiate the topological arguments made above.

As noted before, the N_c = 4 result is the mean-eld result for d-wave order and hence yields the largest pairing correlations and the highest T_c. As expected, we nd large nite size and geometry e ects in small clusters. W hen $z_d < 4$, uctuations are overestim ated and the d-wave pairing correlations are suppressed. In the 8A cluster where $z_d = 1$ we do not nd a phase transition at nite tem peratures. Both the 12A and 16B cluster, for which $z_d = 2$, yield alm ost identical results. Pairing correlations are enhanced com pared to the 8A cluster and the pair-eld susceptibility P_d diverges at a nite tem perature. A s the cluster size is increased, z_d increases from 3 in the 16A cluster to 4 in the larger clusters, the phase uctuations become two-dimensional and as a result, the pairing correlations increase further (with exception of the 18A cluster). W ithin the error-bars (shown for 16A only), the results of these clusters fall on the sam e curve, a clear indication that the correlations which mediate pairing are short-ranged and do not extend beyond the cluster size.

The low-tem perature region can be tted by the KT form $P_d = A \exp(2B = (T T_c)^{0.5})$, yielding the KT estim ates for the transition tem peratures T_c^{KT} given in table I.W ealso list the values $T_{\rm c}^{\rm lin}$ obtained from a linear t of the low tem perature region, which is expected to yield m ore accurate results due to the mean-eld behavior of the DCA close to $T_{\rm c}$ [12]. For all clusters with $z_{\rm d}$ 3 we nd a transition temperature T_{c} 0**:**023t 0:002t from the linear ts. We cannot preclude, how ever, the possibility of a very slow, logarithm ic cluster size dependence of the form $T_c(N_c) = T_c(1) + B^2 = (C + \ln (N_c) = 2)^2$ where $T_c(1)$ is the exact transition tem perature. In this case it is possible that an additional coupling between Hubbard planes could stabilize the transition at nite tem peratures.

In sum m ary, we have presented DCA/QMC simulations of the 2D H ubbard m odel for clusters up to N_c = 32 sites. Consistent with the M emm in-W agner theorem, the nite tem perature antiferrom agnetic transition found in the N_c = 4 simulation is system atically suppressed with increasing cluster size. In small clusters, the results for the d-wave pairing correlations show a large dependence on the size and geom etry of the clusters. For large enough clusters how ever, the results are independent of the cluster size and display a nite tem perature instability to a d-wave superconducting phase at T_c 0.023t at 10% doping when U = 4t.

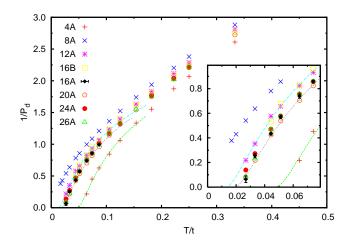

FIG. 3: Inverse d-wave pair-eld susceptibility as a function of temperature for di erent cluster sizes at 10% doping. The continuous lines represents to the function $P_d = A \exp (2B = (T T_c)^{0.5})$ for data with di erent values of z_d . Inset: M agni ed view of the low-temperature region.
