(D ated: A pril 14, 2024)

The autocorrelation of angle resolved photoem ission data from the high temperature superconductor  $B_{1/2} S_{1/2} C a C u_2 O_{8+}$  shows distinct peaks in m on entum space which disperse with binding energy in the superconducting state, but not in the pseudogap phase. A lthough it is tempting to attribute a non-dispersive behavior in m on entum space to some ordering phenomenon, a de-construction of the autocorrelation reveals that the non-dispersive peaks arise not from ordering, but rather from the tips of the Ferm i arcs, which them selves do not change with binding energy.

A central issue in condensed m atter physics is the com petition between di erent order param eters. This com petition is most evident in the transition metal oxides, which show a rich variety of insulating, conducting, magnetic and superconducting phases. In the case of the high tem perature cuprate superconductors, the situation is particularly interesting, with a much debated pseudogap phase lying between the insulating state at zero doping and the d-wave superconducting state. Recent Fourier transform scanning tunneling spectroscopy (FT-STS) experim ents on  $B_{i_2}Sr_2CaCu_2O_{8+}$  have been interpreted [1] in term s of local charge ordering in the pseudogap phase. Here, using an autocorrelation analysis of angle resolved photoem ission spectroscopy (ARPES) data, we dem onstrate that the vectors observed in FT-STS originate from the high density of states at the tips of the dispersionless Ferm i arcs, and not from charge ordering.

The samples employed in this work are single crystals and thin  $\ln \text{ samples of B}_{\frac{1}{2}}\text{Sr}_2\text{CaCu}_{2O}_{8+}$  grown using the oating zone method and RF sputtering technique, respectively. The samples were mounted with the Cu-O bond direction parallel to the photon polarization, and cleaved in situ at pressures below our measurement limit of 2x10<sup>11</sup> Torr. The incident photons were not aligned along a mirror plane to avoid strong selection

rules. M easurem ents were carried out at the Synchrotron Radiation Center in Madison, W isconsin, on the U1 undulator beam line, at 2 m eV intervals, using a Scienta SES 2002 electron analyzer. A momentum resolution of  $0.0036 \text{ A}^{-1}$  was used for the thin Im s, and  $0.01 \text{ A}^{-1}$ for the single crystals, both with a photon energy of 22 eV, with data covering up to four times the irreducible zone in reciprocal space. Both values of the momentum resolution, at least along the detector cut, are com parable to or better than that obtained by FT-STS, which for the largest eld of view studied is about 0.01 A  $^1$  . It should be noted that the resolution values quoted are along the momentum multiplexing direction of the detector, but these detectors have worse momentum resolution along the perpendicular direction (  $0.02A^{-1}$ ). Finally, the spectra were normalized at high binding energies to elim inate the e ect of the dipole matrix element on the intensities.

W hen producing the 2D autocorrelation m aps, we took into account the fact that the data are taken over a – nite range of m om enta, since the number of data points in the autocorrelation sum contributing to a given vector q decreases with increasing q. We deal with this in two di erent ways. The rst m ethod is to norm alize the autocorrelation function by the number of points used

in the sum . The second method is to impose periodic boundary conditions, although we do not display these here. A nother aspect of the data from the single crystals is the presence of photoelectron di raction in ages (superlattice signal) that gives rise to ghost features in both the intensity m aps and their autocorrelations. For these samples, we solve this problem by using only data in the Y quadrant, where the superlattice contribution is well separated from the main state, and reconstruct the whole B rillouin zone by re ections, which require interpolation of the data to a uniform grid. The large background em ission in ARPES reduces the contrast in the autocorrelation m aps. W e deal with this by simply zeroing out the intensity once it falls below a given threshold value, which we take to be 20% for the superconducting phase and 38% for the pseudogap phase, but we em phasize that this procedure does not change the results.

In Fig. 1a and b, we show the ARPES intensity maps, I (k;!), as a function of the momentum k in the rst zone, for two di erent choices of the binding energy !. These data are obtained for an optimally doped single crystal sample ( $T_c = 90$  K) in the superconducting state (T = 40 K). The characteristic banana shapes of the constant energy contours due to the d-wave energy gap can be clearly seen, with the size of the bananas increasing with increasing binding energy. In the right panels c and d, we plot the autocorrelation C (q;!) =  $_k A (k+q;!)A (k;!)$  of the ARPES intensities, i.e., the product of intensities at two di erent momenta at xed energy, separated by a momentum transfer q, sum m ed over the B rillouin zone.

As we shall show in the remainder of this paper, the autocorrelation, which is electively the momentum – resolved joint density of states, permits us to gain in – portant new insights. C (q;!) clearly exhibits discrete spots in q-space, very similar to peaks seen in FT-STS experiments [2]. We note that the ARPES autocorrelation does not require any theoretical modeling for its interpretation, and the observed q-space pattern can be directly interpreted from the measured ARPES intensity I (k;!). By restricting the autocorrelations over speciregions of the intensity maps (as we shall show), we can unam biguously determ ine the origin of those spots.

This analysis reveals that the spots in the autocorrelations, Fig. 1c (and d), originate from the corresponding q vectors spanning the high intensity points of Fig. 1a (and b respectively). In other words, the autocorrelation highlights regions of high density of states as can be seen by m atching the spots in Fig. 1c, e.g., with the arrows spanning the highest intensity areas in Fig. 1a. W e also see that the characteristic q-vectors disperse as a function of the binding energy !. This dispersion is shown in detail in Fig. 1e for the vectors  $q_1$  and  $q_5$ along the bond direction, and in Fig. 1f for the vectors  $q_3$  and  $q_7$  along the zone diagonal. These autocorrelation spots always follow the end of the bananas

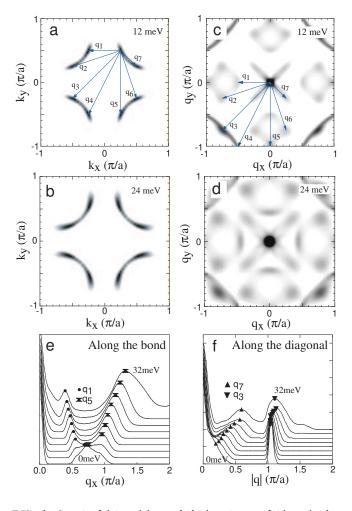

FIG.1: Spectral intensities and their autocorrelations in the superconducting state (T = 40 K) for an optimally doped single crystal sample. Intensity at a binding energy of (a) 12 m eV and (b) 24 m eV in the rst zone. (c)-(d) A utocorrelation of the data in (a)-(b), with vectors in (c) indicating local m axim a in the autocorrelation which correspond to equivalent vectors shown in (a). The gray scales in these plots are in arbitrary units. (e) A utocorrelation of the data as a function of binding energy along the (q;0) direction. The low est curve is at zero energy, with the binding energy increasing by 4 m eV for each subsequent curve (the curves are displaced vertically for clarity). (f) Same as (e), but along the (q;q) direction. For both directions, strongly dispersing peaks are seen.

at each !. Rem arkably, these q-vectors are in quantitative agreement with those obtained by the Davis group [2, 3], and therefore con m that the \octet" model [4] used to explain the FT-STS results does indeed describe the regions of highest density of states. It is surprising that FT-STS shows the same q-vectors, given that the formula used to theoretically model the FT-STS data,  $[Im_k \hat{G}(k+q;!)\hat{T}(k+q;k;!)\hat{G}(k;!)]_{11}$  (where  $\hat{G}$  are N am bu G reens functions), which describes the scattering of electrons from the state k to the state k+q by the scattering m atrix  $\hat{T}$ , is not m athem atically equivalent to the simple autocorrelation used in our analysis.

We now turn to the much less understood pseudogap phase. In Fig. 2 we show data similar to that shown in Fig. 1, but now in the pseudogap phase at T = 90 K of a thin In sample with a  $T_c = 76 \text{ K}$ . The most significant feature of the intensity plots in Figs. 2a and b is that the \Ferm iarcs" [5], the locus of gapless excitations in the pseudogap phase, do not signi cantly change with binding energy, in sharp contrast to the d-wave superconducting bananas [3]. This unexpected behavior is evident in a comparison of the arc lengths in the ARPES intensity m aps in Figs. 2a, b. The autocorrelation of these data along the bond direction are shown in Fig. 2c and exhibit clearly identiable peaks near q = (0:4 = a; 0). Further, as shown in Fig. 2c these autocorrelation peaks show very little dispersion, in m arked contrast to the superconducting state results of Fig. 1. This is the same wavevector observed by FT-STS [1] in the pseudogap phase.

W e now use our intensity data to understand the origin of the dispersionless autocorrelation peaks seen in the pseudogap phase. We nd that these peaks are located at vectors connecting the ends of the Ferm i arcs [5], where there is a sudden on set of the pseudogap. This on set is su ciently steep so the Ferm i arcs have nearly constant length for all binding energies sm aller than the pseudogap value. This gives rise to the dispersionless nature of the autocorrelation vectors. We arrive at this conclusion by truncating the intensity plots to include only the Ferm i arcs, as shown for 0 and 20 m eV in Fig. 2d and e. W e nd that the autocorrelation of these data, shown in Fig. 2f, yields the same result as in Fig. 2c. Therefore, we conclude that q connects the ends of the Ferm iarcs, rather than the parallel sections near the zone faces, whose faint traces can be seen in Fig. 2a and b. This observation also explains why if a q spanning the shorter distance between arc tips is present, q , spanning the longer distance between arc tips along the bond direction, must also be present, as seen in our autocorrelation plot along the bond direction in Fig. 2c. The latter q does not appear in the data of Vershin in et al.[1], but has been seen in later m easurem ents (A. Yazdani, private com m unication). We also nd additional peaks along the diagonal direction, as shown in the autocorrelation surface plot in Fig. 3d. These originate from vectors analogous to  $q_3$ and  $q_4$  in the superconducting state, which span the ends of the arcs along or near the diagonal directions. We have no explanation at present why these peaks are absent in the FT-STS data, though we note that in the superconducting FT-STS data, the intensity of these peaks drops sharply with reduced doping [6].

W hile the octet models and variants have been proposed to explain the FT-STS observations in terms of scattering of electrons by in purities in the superconducting state [2, 4, 7, 8], these models do not describe the pseudogap data [9]. On the other hand, an autocorrelation analysis of ARPES data does not require a model

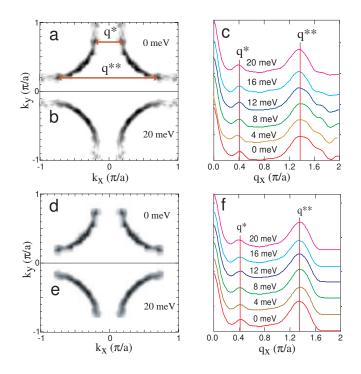

FIG.2: Ferm i arcs in the pseudogap state and their autocorrelations. Spectral intensity in the top half of the st zone at (a) 0 m eV and (b) 20 m eV for an underdoped thin  $\mbox{ Im}$ sam ple (T  $_{\rm c}$  = 76K ) at T = 90 K . O ne can see that the length of the arcs remains unchanged over the energy scale of the pseudogap. (c) Autocorrelation as a function of binding energy along the (q,0) direction. Note the dispersionless nature of the peaks labeled q and q. (d) Spectral intensity as in (a), but with regions beyond the Ferm i arcs cut o from the data. (e) Spectral intensity as in (b), but with the data cut o as in (d). (f) Autocorrelation of the data but with data beyond the Ferm i arcs cut o , as shown for two energies in (d) and (e). Note that the results are unchanged from (c) for the q and q peaks, indicating that the peaks in the autocorrelation originate from the ends of the arcs, and not from the pseudogapped sections of the Ferm i surface.

for its interpretation, which leads us to our most signi cant nding: all features { in both the superconducting and pseudogap cases { have a common origin. They are associated with the k-dependent high density of states, either at the ends of the constant energy contours in the superconducting state (the \bananas"), as rst suggested by H o m an et al.[2], or at the tips of the Ferm i arcs in the pseudogap phase, as we show here. This is in spite of the dram atic di erences between the autocorrelation m aps in the superconducting state, shown in Fig. 3b and in the pseudogap phase, shown in Fig. 3d.

C om paring our ndings to those of FT-STS is useful, in that it directly addresses the question of charge ordering. In principle, collective e ects can appear in the FT-STS m aps [10, 11]. But in ARPES, these e ects would show up as so-called \shadow " bands, that is, in ages of the \bananas" or \arcs" translated by the presum ed ordering

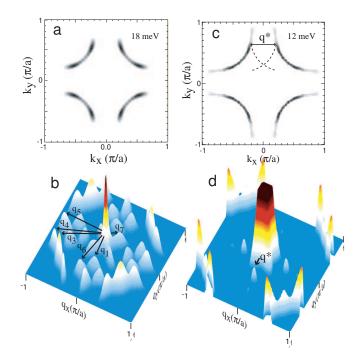

FIG. 3: C om parison of the resulting autocorrelations of similar intensity m aps in the superconducting and pseudogap phases of a single crystal sam ple ( $T_c = 90 \text{ K}$ ). (a) Intensity m ap in the superconducting state at T = 40 K at 18 meV. (b) Surface plot of the autocorrelation function from (a). (c) C om parison of an equal length Ferm i arc in the pseudogap state (T = 140 K) at 12 meV to the superconducting banana in (a) obtained from the same sample. The dashed lines in (c) represent the arcs displaced by the wavevector q identied in Fig. 2a, which are not present in the intensity m aps, but would be if q was due to charge ordering. (d) Surface plot of the autocorrelation function from (c). Note the significant di erences between the two autocorrelation m aps, (b) and (d), despite the sim ilarities of the intensity m aps, (a) and (c).

wavevector (the q ofFig.2c), as indicated by the dashed curves in Fig.3c. But clearly, we nd no evidence for these shadows in Fig.3c at the wave vectors in question in the FT-STS and ARPES autocorrelation maps. The di erence between our conclusions and those of Ref. [12] is the result of their assumption that the Ferm iarc length increases with energy, which it does not in the actual ARPES data.

In summary, while the dispersionless q spots in the

pseudogap phase have previously been interpreted as evidence for charge ordering [1, 3], we show that this dispersionless behavior is simply a joint density of states e ect. The pint spectral density has peaks at q-vectors which connect points of large density of states, namely at the ends of the constant energy contours (\bananas") in the superconducting state, and at the tips of the Ferm iarcs in the pseudogap state. The ARPES autocorrelation peaks are in quantitative agreem ent with the FT-STS results both above and below  $T_c$ . The peaks are dispersionless in the pseudogap phase because the length of the Ferm i arc itself changes very little with binding energy. Therefore we argue that the peaks in the FT-STS data must also arise from density of states e ects, and not charge ordering. It is an interesting open question whether or not the low tem perature FT-STS data on highly underdoped samples of a di erent material,  $C_{2,x} Na_{x}CuO_{2}C_{2,x}$  [13], can also be understood within this picture.
