(Dated: March 23, 2022)

The electronic and vibrational density of states of a semiconducting carbon nanotube in a crossed junction was investigated by elastic and inelastic scanning tunneling spectroscopy. The strong radial compression of the nanotube at the junction induces local metallization spatially confined to a few nm. The local electronic modifications are correlated with the observed changes in the radial breathing and G-band phonon modes, which react very sensitively to local mechanical deformation. In addition, the experiments reveal the crucial contribution of the image charges to the contact potential at nanotube-metal interfaces.

Single-wall carbon nanotubes (SWCNTs) are highly attractive components in nano-scale electronics such as high-performance field-effect transistors [1] or electrical interconnects [2]. The successful implementation of advanced device functions into nanotubes will critically depend on the availability of methods that allow to tune the tubes' electronic properties in a well-defined and spatially controllable manner. One possibility to reach this goal is to use conformational changes, which are well-documented to alter the electronic properties of the nanotubes. Such changes can be induced locally by e.g. mechanical interactions. When a nanotube encounters topographic obstacles like steps in the substrates, electrode lines or other nanotubes, deformations like bends or kinks are introduced into the tube which can result in the local formation of tunnel barriers [3, 4] or other electronic modifications [5, 6]. Alternatively, the tip of an atomic force microscope can be used to alter the electronic structure of a nanotube via mechanical manipulation with spatial control in the nanometer range [7]. In order to take full advantage of nanomechanical interactions to control the electronic properties of nanotubes and thereby tailoring nanodevices, a detailed microscopic understanding of mechanical nanotube contacts is mandatory.

Particularly favorable configurations to study these contacts are crossed junctions between nanotubes. The interaction between the tubes is well defined and spatially localized. Theoretical calculations predict a delicate interplay between the structural deformation and the electronic properties of the nanotube junction [5, 6] with rich physics ranging from band gap modifications through the formation of localized states to metal-semiconductor transitions. Experimentally crossed nanotube junctions can be addressed by scanning tunneling microscopy, but very few studies have been reported so far [8]. Here we report on the simultaneous experimental determination of the local changes in the electronic and vibrational properties in an individual semiconducting SWCNT induced by its bending over a thin SWCNT bundle. The electronic and vibrational response to local mechanical distortions

is mapped with atomic resolution via elastic and inelastic tunneling spectroscopy [9]. Both, electronic and phonon density of states are found to react very sensitively to local tube deformations. Most remarkably, we demonstrate a local metallization of the semiconducting nanotube at the crossing point.

In our experiments, as-produced HiPco (tubes@Rice) SWCNTs have been ultrasonically dispersed in 1,2-dichloroethane and deposited on Au/mica substrates. The samples have been transferred into an UHV system equipped with a home-built STM, and tunneling experiments performed at 6 K using an iridium tip. Recording the first and the second derivative of the tunneling current allows for spatial mapping of the electronic and vibrational density of states with atomic resolution [9].

A topographic image of the investigated SWCNT crossing a bundle, with an apparent height of 14 Å, is depicted in figure 1b. To identify this tube, the procedure described by Wildöer [10] was followed. Using the energy distance between the first van Hove singularities (0.88 eV, 1a), combined with the chiral angle obtained from the topographic image (fig.1b), allows the assignment to the semiconducting (9,2) tube. The line profile, shown in figure 1c, indicates that the tube does not follow closely the contour of the bundle below. Three regions can be distinguished along the tube: in region (I) the tube lies directly on the gold surface, while in region (II) it is lifted from the substrate and suspended between the Au surface and the SWCNT bundle. Finally, in region (III) the tube starts to bend over the bundle. The corresponding topography is schematically illustrated in figure 1d.

Within region (III), which contains the intersection point between the (9,2) tube and the bundle, a striking change in the electron density of states is recognized (figure 1a). The conductivity at the Fermi level is considerably enhanced, and the original energy gap no longer visible, indicating that the nanotube assumes metallic character in this region. Shortly after the crossing point, the initial semiconducting character of the (9,2) tube

is restored, which demonstrates the very local character of the metallization. While previous work reported strong perturbations of the electron density of states and the formation of tunneling barriers as a consequence of tube crossings or interaction with patterned substrates [4, 11, 12], the local metallization of a semiconducting tube has not yet been observed.

Before discussing in detail this local metallization we first analyze the electronic and vibrational structure of the adsorbed and freely suspended tube segments. Within the suspended region (II), it can be seen that the van Hove singularities in the valence and conduction bands experience a shift of approximately 60meV towards higher energy with respect to their position in region (I). This shift occurs mostly within the first 3nm of region (II), which is followed by a much weaker dependence with increasing distance from the substrate. The nanotube-metal substrate interface has been subject of several theoretical investigations. According to these, the difference in work-function between the two materials leads to charge transfer across the metal-tube interface. The resulting charge accumulation layer in the nanotube and its image-charge in the metallic substrate give rise to a contact potential $\Delta = \Delta_{Holes} - \Delta_{Images}$ at the interface which affects the alignment of the nanotube bands, causing their displacement towards higher energies [13, 14]. The charge density at the interface decays only logarithmically with the distance [15, 16], due to the ineffective Coulomb screening in a quasi one-dimensional nanotube. Hence, in first approximation, the charge density in the nanometer-long suspended segment can be assumed as constant. The increasing distance to the substrate weakens, however, the screening effect of the image-charges (figure 1c), leading to an apparent excess charge on the nanotube and thus to an increased contact potential at the interface $\Delta' = \Delta + \delta$, which shifts the bands further towards higher energies (figure 1c).

The modified capacitive coupling of the substrate-nanotube-tip system, in the suspended region, can be addressed in analogy to double barrier tunneling junctions [17]. Using the relation $\Delta V = \Delta Q / C_{TS}$ where ΔV is the voltage shift, ΔQ the fractional charge at the interface and C_{TS} the tube-substrate capacitance, the unscreened charge can be estimated from the measured shift of the valence band singularity. For the capacitance C , we apply the model of a finite wire of length L at a distance z from a conducting plate $C = 2\pi\epsilon_0\epsilon_r L / \ln(4z/d)$ [18]. Considering the measured energy shift of 60mV, an averaged tube-substrate distance of 1nm, a length of 3nm for the tube section within which most of the shift occurs, and assuming $\epsilon_r = 2$, the reduced screening is associated with an additional charge of 0.08 holes on the suspended tube segment. Noting that theoretical predictions estimate that, upon bringing the nanotube into contact with a gold surface, 0.3 holes are transferred in the same tube length [19], the reduced screening of the image-charge is equivalent

to an additional 26% of the total charge transferred at the interface. This result suggests that the contact potential at the tube-metal interface is determined not only by the difference in the work functions, but also significantly influenced by the image-charge. This property places the nanotube interface at an intermediate position between the bulk inorganic semiconductor-metal interface, where the image-charge influences only marginally the contact barrier, and the organic semiconductor-metal interface, where the contribution of the image-charge is comparable to the built-in potential [20].

The behavior of the most prominent phonon modes, namely the radial breathing mode (RBM) and the G-band apparent from the corresponding IETS maps (figure 2), which display the total phonon density of states as a function of position along the tube axis. In view of the low sensitivity of the G-band and of the RBM to charge doping [21, 22], it is not expected that the small additional charge in the tube segment of region (II) ($\sim 1 \times 10^{-4}$ holes per carbon atom) shifts these modes significantly. As can be seen in figure 2a, the G-band, which consists of 6 unresolved vibrational modes [23] corresponding to lattice displacements in the circumferential direction (tangential modes) and along the tube axis (longitudinal modes), occurs in region (I) between 190 and 200 meV. Within region (II), the energy position of the longitudinal modes stays constant while a gradual decrease of the intensity of the tangential displacements is observed. A similar observation has been made in case of chemically doped carbon nanotubes [23]. The RBM, which comprises the in-phase radial displacement of the carbon atoms and whose energy scales inversely with the tube diameter occurs on the metal substrate at an energy of 32meV (see figure 2b), in good accordance to the value expected for the (9,2) tube with a diameter of 8.1Å [9]. Within region (II), the RBM experiences a slight downshift by about 1.5meV as compared to region (I). This downshift can be attributed to the reduced interaction forces with the substrate as a result of lifting the tube. The importance of the surrounding is well-documented in nanotube bundles, where van-der-Waals interactions cause stiffening of the RBM [24]. For the (9,2) tube, the RBM is expected to harden by 6% due to these interactions with respect to the free-standing tube. Although the van-der-Waals interaction of the tube with the surface is not isotropic as in a nanotube bundle, the experimentally observed decrease in the RBM energy of 1.5meV upon entering region (II), is largely consistent with the estimated value of 1.9meV.

The metallization observed in region (III) is ascribed to a local compression of the tube. The van der Waals forces attracting the upper tube to the substrate result in a large local pressure at the crossing region. This causes an elliptical shape of the tube as can be deduced from the line profile (figure 1c) showing a height that is

about 35% smaller than the sum of the apparent heights of the tube and the crossed bundle. The compressibility of the tube, which is described by the bulk modulus B , provides for an estimate of the pressure P imposed at the crossing junction through the infinitesimal relation $dP = -dV/VB$, where V is the volume. Assuming that the attractive van-der-Waals forces between the upper nanotube and the surface squeeze the tube cross-section into an elliptical shape at the crossing point, and using a bulk modulus of 35 GPa [25], the pressure necessary to obtain a volume reduction of 35% is estimated to 15 GPa. This pressure is in reasonable agreement with that predicted by first principle calculations [3] for nanotubes at crossing-junctions. It is remarkable that for the (9,2) tube, an elliptical cross section with an axis ratio of 0.65 implies a short axis length that is very close to the theoretically predicted 4.6 Å necessary to induce a semiconductor-metal transition [5]. It is therefore likely that the observed tube metallization is induced by the local structural change. The strong deformation of the nanotube at the crossing junction is reflected in the behavior of the phonon density of states in region (III). In particular, the G-band is completely suppressed within region (III) (figure 2a). This observation agrees well with results from high pressure Raman studies, which demonstrated a strong attenuation of the G-band above 10 GPa and its complete vanishing at 20 GPa as a consequence of the strong radial compression of the SWCNTs [26]. The energy of the RBM rises to the value of 37 meV at the crossing point (figure 2b) and quickly restores afterwards. The observed energy variation of the RBM between the suspended and the compressed region (~ 7 meV) is lower than the value expected from Raman investigations reporting an increase by 1.1 meV/GPa. However, it is noticed that the present study addresses effective pressures well above 2 GPa, which represents the maximum that could so far been investigated by Raman spectroscopy due to the loss of the resonance enhancement. Hence, it cannot be excluded that the energy vs. pressure dependence of the RBM would assume a significantly weaker slope in the high pressure regime, or that the non-hydrostatic pressure affects the RBM in a different manner. In figure 2b, one furthermore observes a "wiggle" (local minimum) in the energy dependence of the RBM at the left border of region (III), where the first and the second tube of the bundle are touching. This behaviour further illustrates the extreme sensitivity of nanotube phonon modes to local mechanical interactions.

In conclusion, the combination of elastic and inelastic scanning tunneling spectroscopy techniques has revealed a correlation between changes of the local electron and phonon density of states of a semiconducting SWCNT, induced by the bending of the tube over a thin nanotube bundle. In the suspended tube region, the observed shift of the valence band towards the Fermi energy has been

attributed to an effective hole doping resulting from reduced screening of the charge accumulation layer by the metal substrate. Around the crossing point, the tube achieves a metallic character. This striking observation has been attributed to the strong local radial compression, which is corroborated by the observed increase in the RBM energy as well as the complete disappearance G-band in this tube region.
