Classical limit of transport in quantum kicked maps

Saar Rahav and Piet W . Brouwer

Laboratory of Atom ic and Solid State Physics, Cornell University, Ithaca 14853, USA.

We investigate the behavior of weak localization, conductance uctuations, and shot noise of a chaotic scatterer in the sem iclassical lim it. T in e resolved num erical results, obtained by truncating the tim e-evolution of a kicked quantum map after a certain number of iterations, are compared to sem iclassical theory. Considering how the appearance of quantum e ects is delayed as a function of the Ehrenfest tim e gives a new method to compare theory and num erical simulations. We end that both weak localization and shot noise agree with sem iclassical theory, which predicts exponential suppression with increasing Ehrenfest time. However, conductance uctuations exhibit di erent behavior, with only a slight dependence on the Ehrenfest time.

I. IN TRODUCTION

A coording to E hrenfest's theorem, the expectation values of the position and momentum of an electron obey classical equations of motion. As long as the wavefunction of the electron is a wavepacket with minimal uncertainties in momentum and position, the expectation values are a good description of the quantum state. However, wavepackets disperse, and the Ehrenfest theorem looses its relevance after a short time. In a cavity with point scatterers, which split electron wavepackets into partial waves after one scattering event, this time is simply the elastic mean free time. In a ballistic cavity with chaotic classical dynamics, this time is the so-called E hrenfest time" _E, which depends on the Lyapunov exponent of the classical motion in the cavity.¹^{,2} For times longer than E, a classical description no longer holds and the wave nature of the electrons becom es visible.

The wave nature of electrons is the cause of som e striking e ects that are absent in classical system s. For transport through cavities coupled to source and drain reservoirs via point contacts, these e ects are weak localization, universal conductance uctuations, and shot noise.³ In the lim it that transport through cavities is ergodic (dwell time in the cavity is much longer than the time of ight through the cavity), the signatures of quantum transport are universal', independent of the cavity size and shape, and of the fact whether electron motion inside the cavity is ballistic and chaotic or di usive, with repeated scattering o impurities with size smaller than the electron wavelength. R andom m atrix theory provides a uni ed theoretical description of weak localization, universal conductance uctuations, and shot noise in ballistic or di usive cavities.4

If the electron m otion is di usive, the dynam ics is fully quantum m echanical already at times much shorter than the time $_{erg}$ required for ergodic exploration of the cavity's phase space. For ballistic cavities this is true in m ost practical applications as well | the Ehrenfest time $_{E}$ usually does not exceed the time of ight through the cavity | but there is no fundam ental reason why $_{E}$ always has to be sm all. The case of large Ehrenfest times is

of theoretical interest, as it is one of very few regimes in parameter space in which one can observe di erences between signatures of quantum transport in ballistic chaotic and di usive cavities.

The most prominent e ects of a large Ehrenfest time are found if $_{\rm E}$ is larger than the dwell time $_{\rm D}$ in the D, quantum transport is determ inistic, cavity. If E and shot noise is suppressed.^{5,6} The suppression of shot noise has been observed experim entally by varying the dwelltime $_{\rm D}$ of a chaotic cavity,⁷ and num erically, using a chaotic m ap as a m odel for a chaotic cavity.^{8,9,10} The e ect of a large Ehrenfest tim e on weak localization was rst addressed by A leiner and Larkin.² Their theory predicts a suppression of weak localization / exp $(E_{\rm E} = D)$, if classical correlations are taken into account properly.¹¹ The same suppression was found in an independent calculation by Adagideli.¹² Experim ental observation of the suppression of weak localization at large Ehrenfest times has been reported for transport through antidot arrays.¹³ No sem iclassical theory for the Ehrenfest-time dependence of universal conductance uctuations exists. How ever, sem iclassical theories for weak localization and universal conductance uctuations for the lim it D F are essentially equal,^{14,15,16,17} as are diagram matic perturbation theories for the same phenomena in di usive cavities, supporting the expectation that the Ehrenfest-time dependencies of weak localization and universal conductance uctuations will be equal as well.¹⁸

D irect numerical simulation of the e ect of a large Ehrenfest time on quantum transport through twodimensional chaotic cavities has been problematic because of the prohibitively high computational cost of the simulations. The reason is that $_{\rm E}$ depends only logarithm ically on the product of the electron wavenum berk and the cavity size L,

$$E = {}^{1} \ln kL: \qquad (1)$$

For two-dimensional cavities, system sizes at which $_{\rm E}$ > $_{\rm D}$ cannot be simulated with present-day algorithms and processor speeds. In order to circum vent this problem, Jacquod, Schomerus, and Beenakker proposed to replace the cavity by a quantum map.¹⁹ The map is 'opened',

so that simulation of transport properties is possible. Although a map has a one-dimensional phase space, a chaotic map shares many characteristics of the chaotic motion in two-dimensional chaotic cavities.²⁰ The reduced dimensionality of the map's phase space made num erical simulations with larger Ehrenfest times possible. For an open version of the quantum kicked rotator map, num erical simulations were reported for shot noise,^{8,9,10} weak localization,^{11,21} and universal conductance uctuations.^{9,18,22} Simulation results for shot noise were in good agreem ent with the predictions of the sem iclassical theory.⁶ However, for conductance uctuations, no dependence on $_{\rm E}$ was found, despite the fact that Ehrenfest times larger than the dwell time were considered.²³ W hereas early num erical simulations of weak localization showed no Ehrenfest-time dependence, 21 we show ed that there is a system atic decrease of the weak localization correction to the conductance upon increasing $_{\rm E}$, consistent with the sem iclassical theory.¹¹

The main technical innovation that allowed us to detect a system atic decrease of the weak localization correction upon increasing the Ehrenfest time is that we looked at tim e-resolved num erical sim ulations: The m ap's tim e evolution is truncated after a time to, and weak localization, conductance uctuations, and shot noise are monitored as a function of t₀.¹¹ This procedure has two advantages. First, it allows the ensemble average over the quasienergy " to be done analytically. (See Sec. II for technical details.) This made it possible to consider signi cantly larger ensembles than considered previously. Second, monitoring quantum corrections as a function of the 'truncation time' t_0 allows us to determ ine the minimal time after which quantum corrections can occur. In the sem iclassical theory, quantum interference requires a m in in al wavepacket to be split and reunited, which takes a minimal time 2 $_{\rm E}$. A schematic diagram drawing relevant sem iclassical trajectories for weak localization and conductance uctuations is shown in Fig. 1. (The diagram for conductance uctuations is taken from Ref. 17 and modied to contain the e ect of a nite Ehrenfest time.) Not being a quantum interference e ect, shot noise only requires wavepackets to be split, which happens after a time $_{\rm E}$. C om parison of the time when quantum e ects appear (the 'onset time') and the rate of suppression of quantum e ects as the Ehrenfest time E is increased, thus provides a quantitative test of the sem iclassical theory. W ith such a quantitative test of the sem iclassical theory, accurate simulations perform ed at smaller Ehrenfest times can still be meaningful.

In this paper, we present detailed results of such timeresolved num erical simulation for weak localization, conductance uctuations, and shot noise. For all three quantum e ects, we analyze their Ehrenfest-time dependence (w ithout truncation of the time evolution) and the onset times (obtained from simulations with truncation of the time evolution). The simulation results are presented in Sec. II, together with the predictions of random m atrix theory for time-resolved transport through open quan-

FIG.1: Schem atic drawing of relevant trajectories for weak localization (a), conductance uctuations (b), and shot noise (c). The letters \L" and \R" refer to the left and right contacts to the cavity, respectively. The trajectories shown in panel (a) are for the weak localization to the transmission T; the trajectories shown in panel (b) are for the covariance $cov(R_L;R_R)$ of rejections from the left and right contacts. Both weak localization and conductance uctuations requires a minimal dwell time of 2 $_E$. Shot noise requires a minimal dwell time $_E$ only.

tum maps. W hereas we con rm our earlier conclusion that the num erical simulations for weak localization show a suppression / exp ($_E = _D$), consistent with the sem iclassical theory, we nd that simulations for conductance uctuations show a very small increase if $_E$ is increased, the e ect being small enough to be consistent with the simulation data reported in the literature.^{9,18,22} The onset times for conductance uctuations are more than a factor two smaller than the onset times for weak localization, which is incompatible with the notion that conductance uctuations arise as wavepackets are split and reunited.

A second goal of this paper is to show how classical correlations are taken into account in the sem iclassical theory of R ef. 2. The importance of classical correlations | no quantum di raction takes place to or from classical trajectories with classical dwell time shorter than the Ehrenfest time | was pointed out in the analysis of simulation data for the quantum kicked rotator, most notably the simulations for shot noise.⁸ The original version of the sem iclassical theory,² which did not include these correlations, predicted a suppression of weak localization / exp($2_E = _D$). It is only after accounting for the classical correlations that the proper exponential decay / exp($_E = _D$) is recovered. (Classical correlations are taken into account correctly in the sem iclassical theory of shot-noise suppression at large Ehrenfest times.⁶) In addition it is demonstrated that this sem iclassical theory is unitary, i.e., that no probability is lost. Our discussion of the sem iclassical theory for weak localization can be found in Sec. III. We conclude in Sec. IV.

II. TIME RESOLVED TRANSPORT IN OPEN QUANTUM MAPS

D espite their di erent dimensionality, chaotic quantum maps are believed to have the same phemonology as (closed) chaotic cavities,^{24,25,26,27} provided one restricts attention to the \universal limit" of times longer than the \ergodic time". (The \ergodic time" is the time required to explore the phase space.) Open kicked quantum maps have been used as a model for transport through chaotic cavities,¹⁹ because maps allow to simulate systems with many transport channels with relatively small computationale ort. For short times, qualitative di erences between maps and cavities exist, how ever, because the time evolution in maps is discrete, whereas the time evolution in cavities is not.

Q uantum m aps operate on a nite state vector of dimension M. In the context of the quantum kicked rotator these states are discrete quasim on entum states or, alternatively, positions on a lattice with periodic boundary conditions. In the language of a cavity, the elements of can be thought of as points on the cavity boundary. The time evolution of such m aps is discrete, and given by the F loquet operator

$$(t + 1) = F$$
 $(t):$ (2)

For the kicked rotator, this type of dynam ics is relatively easy to simulate num erically, which is why it is used to num erically model quantum interference corrections at large Ehrenfest times.

In order to study transport, the system has to be opened. Hereto two consecutive sets of N_L and N_R elements are chosen that corresponds to two 'leads'.¹⁹ The initial condition for a transport simulation corresponds to

localized at one of the 'lead' points. Escape from the cavity is modeled by recording the amplitude of at the lead points at time t and setting to zero afferwards. Form ally, this corresponds to the construction^{8,28,29,30}

$$S(") = P 1 e^{i"}FQ e^{i"}FP^{T};$$
 (3)

where S is the scattering matrix corresponding to the map, " is quasienergy, P is a $(N_R + N_L)$ M matrix projecting on the sites corresponding to the left (L) and

$$\begin{array}{ll} G_{RL} & trSC_{L}S^{Y}C_{R}; \\ G_{LR} & trSC_{R}S^{Y}C_{L} \\ G_{LL} & trSC_{L}S^{Y}C_{L} & N_{L}; \\ G_{RR} & trSC_{R}S^{Y}C_{R} & N_{R}; \end{array}$$

where C_R projects on the channels of the right lead, whereas C_L projects on the channels of the left lead. Unitarity im plies $G_{RL} = G_{LR} = G_{LL} = G_{RR}$. The dwell time corresponding to the map is $_D = M = (N_L + N_R)$.

We note that, with this method of opening the map, the leads end abruptly. Such abrupt changes lead to di raction e ects, sim ilar to di raction from sharp corners at the lead opening of a cavity. The sem iclassical contributions of som e di racting orbits of this type were calculated for closed and open cavities, see, e.g., Refs. 31,32,33. They were found to be an important contribution to shot noise at sm all channel num bers N for rectangular cavities.^{34,35} H ow ever, to the best of our know ledge, the total contribution of such orbits to shot noise, weak localization, and conductance uctuations in chaotic cavities at large N are unknown. Therefore, we com pare our num erical results to the existing sem iclassical theory, which neglects the e ects of corner di raction.

In this section, we will study the transm ission and reection coe cients as a function of a truncation time t $_0$. The truncation procedure involves writing Eq. (3) as a geometric series of a time-dependent scattering matrix S (t),

$$S('') = \bigvee_{t=1}^{X^{d}} e^{i''t} S(t);$$
(5)

with

$$S(t) = P [FQ]^{t 1} F P^{T} :$$
 (6)

Instead of taking the full geom etric series (5), we truncate the series after time t_0 ,

$$S (t t;") = e^{i''t} S (t);$$
 (7)

and study transport properties as a function of t_0 . A lthough such a truncation procedure does not represent a physical system, it allows us to get theoretical inform ation on the times involved in quantum transport phenom ena. In particular, we will verify at what truncation time weak localization and conductance uctuations will rst appear.

The quantities of interest are the ensemble-averaged conductance coe cients G_{LL}, G_{RL}, G_{LR}, and G_{RR}, with S replaced by S (t t₀), and the uctuations of these coe cients. With the truncation procedure, S is no longer unitary, so that one does not necessarily have that G_{RL} = G_{LR} = G_{LL} = G_{RR}. Hence, we need to consider all four conductance coe cients separately. If F is

time-reversal symmetric, one still has $G_{\rm R\,L}=G_{\rm LR}$, and only three conductance coe cients need to be considered. For t_0 $_D$, unitarity is restored, and one conductance coe cient is su cient.

It is also of interest to study the t_0 dependence of shot noise. This also can be done by replacing the scattering matrix by S (t t_b), as was done for weak localization and conductance uctuations. The resulting t_0 dependent Fano factor is given by⁸

$$F (t_0) = \frac{N_R + N_L}{N_R N_L} tr SC_R S^{y}C_L 1 SC_R S^{y}C_L : (8)$$

The ensemble average is taken by rst averaging over the quasienergy ", and then over various lead positions. The quasienergy average can be performed explicitly, see Eq. (7) above. For the uctuations, we consider the variances of the transport coe cients, as well as covariances of di erent coe cients. The variances are taken with respect to the quasienergy ", in order to ensure that the uctuations are entirely of quantum origin.^{9,22} The variance or covariance for uctuations with respect to " is then averaged over di erent lead positions. A gain, having the explicit energy dependence (7) at our disposal, the calculation of the variance or covariance with respect to variations of " can be performed explicitly.

A. Random matrix theory of time-resolved transport

As a reference for our num erical simulations, in which we take the F loquet operator F of the quantum kicked rotator, we consider averages and uctuations of the transport coe cients for the case that F is a random symmetric unitary matrix, taken from the circular orthogonal ensemble of random matrix theory. In the limit of large M , N $_{\rm L}$, and N $_{\rm R}$, which is relevant for the sem iclassical limit we consider throughout this paper, such averages can be calculated using the technique of R ef. 36. We then nd

$$hG (t t_{b})i = hG (t t_{b})i_{cl} + G (t t_{b}) + O (M^{2});$$
(9)

where the indices and can be taken to be L and R . The rst term hG $(t_0)i_{c1}$ is the classical average,

hG (t t₀)
$$i_{c1} = \frac{N N}{M} \frac{1 x^{t_0}}{1 x}$$
 N ; (10)

with x = 1 1 = D, and G (t_0) is the weak localization correction,

$$G (t t_0) = \frac{N (1 x^{t_0})}{M (1 x)} \qquad \frac{N N}{M^2} \frac{1 x^{t_0}}{(1 x)^2} \frac{t_0 x^{t_0}}{1 x} + \frac{t_0 (t_0 1) x^{t_0 1}}{2} \qquad (11)$$

For the covariances we nd similarly in the limit of M , N $_{\rm R}$, N $_{\rm L}$ $\,$ 1,

where

$$R_{1} = \frac{2x}{1+x} = 2x^{t_{0}-1} + (t_{0}+1)x^{2} + 6x + 1 = \frac{2x^{2t_{0}-1}}{1+x} + x^{2t_{0}-2}$$

$$= \frac{2}{3}(1-x)^{3}t_{0}^{3} + (1-x)^{2}(1+x)t_{0}^{2} + \frac{1}{3}t_{0}(1-x)(11x^{2} + 20x - 1) + 2x(x^{2} + 5x + 2);$$

$$R_{2} = \frac{x}{1+x} + 2x^{t_{0}} + \frac{x^{2t_{0}-1}}{1+x} + (t_{0}-1)x^{2t_{0}-1} + (t_{0}-1)x^{2t_{0}};$$

$$R_{3} = x - \frac{1}{1+x} + x^{t_{0}-1} + \frac{x^{2t_{0}-1}}{1+x} :$$
(13)

In Eq. (12) the symbol $\cos v_{*}$ denotes a covariance taken with respect to variations of the quasienergy only, whereas the brackets h:::i denote the ensemble average over F.

B. The open quantum kicked rotator

In our num erical simulations, we take the F loquet operator F of the quantum kicked rotator map. The map is described in detail by Tworzydlo et al., see Ref. 21. The m atrix elements of the F loquet operator are

$$F_{mn} = X U^{Y} U X_{mn}$$
(14)

with

$$U_{mn} = M^{1=2} e^{2 \min n = M};$$

$$X_{mn} = m_{n} e^{i \frac{M K}{4} \cos(2 m = M +)};$$

$$m_{n} = m_{n} e^{i m^{2} = M}:$$

Here K is the so called stochasticity parameter that determ ines the classical dynamics of the map. The region K $^>$ 7.5 is associated with classically chaotic dynamics. The parameter determ ines the precise quantization of the map and has no e ect on the classical dynamics. In this model the size of the matrix M is even. In the sim – ulations we set N $_{\rm R}$ = N $_{\rm L}$ = N .

W e used the F loquet operator (14) to study conductance uctuations and shot noise. The F loquet operator (14) can also be used to study weak localization using the following argument: The average conductance hG i consists of a classical contribution and a quantum correction,

$$hG \quad i = G \quad ;cl + G \quad : \tag{15}$$

The classical contribution G $_{;cl}$ scales proportional to the channel number N , whereas the quantum correction has no N -dependence (except for a possible weak dependence on N through the Ehrenfest time). The quantum correction can be extracted by comparing average conductances at N channels and 2N channels,

In order to avoid a spurious contribution to G from classical conductance uctuations, we made sure that the ensem ble averages for hG (2N)i and hG (N)i were taken for precisely the same classical dynamics (same values of K, same lead positions). This method was used previously in Ref.11.

A lternatively, one can study weak localization by considering m aps with and without tim e reversal sym m etry. The kicked rotatorm ap (14) has tim e-reversal sym m etry. A simple extension of Eq. (14) that breaks tim e-reversal sym m etry is the so-called three-kick m odel,²¹

$$F_{mn} = (X Y Y X)_{mn}$$
(17)

where

$$Y_{mn} = m_n e^{i\frac{M}{6}\cos(2 m - M)};$$

$$X_{mn} = m_n e^{i\frac{M}{12}V(2 m - M)};$$

$$m_n = M^{-1=2} e^{i-4} e^{i\frac{M}{M}(n m)^{2}}:$$

In this model M is even, but not a multiple of 3. The kick potential is given by

V () = K cos (q=2) cos
$$+\frac{1}{2}$$
K sin (q=2) sin 2 ; (18)

where q breaks the parity sym m etry of the m odel.³⁷ T he parameter plays the role of a m agnetic eld and breaks tim e-reversal sym m etry. By com paring the transport for

€ 0 to that of = 0 it is possible to investigate the weak localization correction as a function of time. This is the method used in Ref. 21.

The advantage of the second m ethod is that it does not require the cancellation of classical conductances of two di erent systems. The disadvantage is that it involves the additional parameter , which itself also a ects the map's classical dynamics. However, weak localization is a ected on the scale 1=N, so that the e ect on the classical dynamics can be expected to be small in the sem iclassical lim it N 1.

For both m odels, the Ehrenfest time is given by

$$E = {}^{1} \ln N ; \qquad (19)$$

up to an N -independent constant. The dwell time reads

$$_{\rm D} = \frac{\rm M}{2\rm N} : \qquad (20)$$

C. Num erical results

The numerical algorithm used to iterate the maps (14) and (17) can be accelerated by using a fast Fourier transform 8,21,22,38 The results are computed as a function of time and not of quasienergy. This allows to truncate the series (5) at the maximal time studied, and to calculate the "-averages explicitly.

W eak localization. The value of the tim e-reversal sym metry breaking parameter at which weak localization corrections to the conductance are suppressed in the three-kick m odel (17) scales inversely proportional to the channelnum ber N²¹ Hence, in order to com pare weak localization corrections for di erent channel num bers, the average conductance is calculated as a function of the product N.Figure 2 shows the result of num erical sim ulations of the ensemble-averaged conductance. The ensem ble average is taken over 1000 sam ples, choosing K random ly in the interval 10 < K < 11.5 and varying the lead positions. The gure also shows a Lorentzian t to the simulation data for small N. The dwell time is set to be $_{D} = 5$ and the parity-symmetry breaking param eter q = 0:2. Results for di erent N are o set vertically. W hen determ ining the magnitude of the weak localization correction, we restrict our attention to the range N < 1, for which the N-dependence of hG_{LR} i exhibit a pronounced dip. The width of this dip seems to be (alm ost) independent on system size, in agreement with the predictions from random matrix theory.²¹ However, as can be seen from Fig. 2, the shape of this peak is not

well approximated by a Lorentzian at higher values of \cdot . For N > 1 the average conductance typically continues to increase with N, but at a much slower rate.

Figure 3 shows the di erence $G_{\rm LR}$ () = $hG_{\rm LR}$ (0) $G_{\rm LR}$ ()i for N = 0:7, as a function of the cut-o time t_0 . (These results are averaged over 20 000 di erent realizations.) The standard case (w ithout truncation) corresponds to the lim it t_0 ! 1 . Upon increasing N , the gure shows a system atic decrease of $G_{\rm LR}$ as well as a shift of the onset of weak localization to larger truncation times.

To study these num erical result quantitatively, we exam ine the dependence of the onset of weak localization and its magnitude on the number of channels. As an operational de nition of the onset time t_{on} , we de ne t_{on} as that truncation time t_0 for which $G_{LR}(t_0) =$ 0:1 $G_{\rm LR}$ (t_0 !~ 1). In principle, onset times could also have been de ned using $~~\mathsf{G}_{\texttt{LL}}$. W e prefer to use $~~\mathsf{G}_{\texttt{LR}}$, since the latter are less in pacted by the discreteness of the map's time evolution. The left panel of Fig. 4 shows t_{on} as a function of N $\,$ for the simulation curves shown in Fig. 3, as well as for similar curves calculated for N = 0:3 (tim e-resolved data not shown) and for sim ulation data taken at dwell time $_{D} = 10$. The right panel of Fig. 4 shows the dependence of j G_{LR} jon N. Figure 5 depicts the same data as gure 4, but for stochasticity param eter K taken uniform ly in the interval 20 < K < 23.

According to the sem iclassical theory, the derivative $dt_{on} = d \ln N = 2 =$, where is the Lyapunov exponent of the map. Similarly, sem iclassics predicts that dlnjG_{LR}j=dlnN = 1 = D. The classical map corresponding to Eq. (17) is described in Ref. 21, and its Lyapunov exponent is readily calculated using the method described in Ref. 39. Since the magnetic elds that break time reversal invariance are classically sm all, the Lyapunov exponents should be computed for = 0.Numerically, we nd = 1:56 for K 10 and = 2:04 20. Lines with slopes corresponding these Lyafor K punov exponents are shown in Figs. 4 and 5. W e conclude that the N -dependence of j $G_{\rm L\,R}$ j is well described by the sem iclassical theory. The onset tim es deviate som ew hat from the expected slope, how ever. Since this deviation is m ore pronounced for the shorter dwell time we attribute it to uctuations in the values of the Lyapunov exponent. Fluctuations of the Lyapunov exponent have a stronger e ect on quantum corrections at short dwell times than at large dw ell tim es.²

A lthough our data are obtained in the sam e way as in Ref. 21, our conclusions are markedly dierent. W hereas Ref. 21 nds no evidence of a system atic Ehrenfest-time dependence of weak localization, we conclude that there is a system atic Ehrenfest-time dependence of weak localization and that the simulation results for weak localization are consistent with the sem iclassical theory. W e attribute the dierences to a lack of accuracy in the simulations of Ref. 21. Indeed, on average the simulations of Ref. 21 do show a slight decrease upon increasing N, but the statistical uncertainties are too large to rule whether

FIG.2: A verage conductance for the three-kick m odel (17) as a function of the tim e-reversal sym m etry breaking param eter N. Curves shown for N = 25;50;100 and 200 are o set vertically. The stochasticity param eter K 10, q = 0.2, and the dwell tim e $_{\rm D}$ = 5. Inset: Sam e for a larger range of N values.

FIG.3: Time-resolved di erence between ensem ble-averaged conductance at N = 0 and N = 0.7 for the three-kick model (17). The dwell time is $_{\rm D}$ = 5, while K 10 and q = 0.2

the decrease is system atic or accidental.

Figure 6 shows time-resolved data for G_{LR} for $_{D} = 12.8$, q = 0.3, N = 0.2, and K taken uniform by in the interval 10 < K < 11.5. W hereas the simulation data are consistent with the sem iclassical theory for $N \ge 20$ (see the insets in Fig. 6), the simulation results for G_{LR} show signi cant deviations from the sem iclassical theory for sm aller channel num bers. This is no surprise, as the sem iclassical theory is known to break down for sm all N. D expite the di erences between the sem iclassical theory and the magnitude of the simulated weak localization correction G_{LR} for sm all N, the onset times appear to depend linearly on ln N down to the sm allest channel num bers considered in the simulation (N = 5).

The second method of computing weak localization uses the scaling of the conductance with the number of

FIG.4:Left:Onsettimeton obtained from the time-resolved di erence G_{LR}() G_{LR}(0).Right:Weak localization correction G_{LR}, together with a t / exp($_{E}=_{D}$). The stochasticity parameter K uniform ly chosen between 10 and 11:5; the dwelltimes $_{D}$ is set at $_{D}$ = 5 and $_{D}$ = 10.For $_{D}$ = 5, data are shown for N = 0:7 (circles), and N = 0:35 (squares). For $_{D}$ = 10, data are shown for N = 0:3 (diamonds) and N = 0:15 (triangles).

FIG.5: Sam e as Figure 4, but for K random ly chosen between 20 and 23.

channels, see Eq. (16). Tim e-resolved results for re ection and transm ission coe cients are shown in Fig.7 and 8, with K taken random ly from the interval 10 < K <11:5 and dwell times $_{D}$ = 5 and $_{D}$ = 10, respectively. For $_{\rm D}$ = 5, an average was taken over 80000 sam ples, except for the data point at N = 400. Due to the num erical cost of the calculations for N = 400 only 40000 sam ples were considered for K 10 and 20 000 sam ples 20. For $_{\rm D}$ = 10, the average was taken over for K 20000 sam ples for K 10 and over 40 000 sam ples for 20. In all cases the statistical error of the weak lo-Κ calization correction was estimated to be 10^3 . Again, we compare the data in Fig. 9 to lines with slopes which are xed by the Lyapunov exponent of the corresponding classical map. For this model the Lyapunov exponents are 1:69 when K 10 and 2:37 when K 20. As for the three-kick model, the results are consistent with the

FIG.6: T in e-resolved di erence between ensem ble-averaged conductance at N = 0 and N = 0.2 for the three-kick model (17), for K 10 and $_{\rm D} = 12.8$. Left inset: onset times. Right inset: weak localization correction.

FIG.7: W eak localization correction to re ection and transmission coe cients, obtained using Eq. (16). D ata shown are for K 10 and $_{\rm D}$ = 5. The average was taken over an ensemble of 80 000 realizations, except for N = 400, as described in the text.

sem iclassical theory, see the right panel of Fig. 9. Figure 9 also contains results for K taken uniform ly in the interval 20 < K < 23 (tim e-resolved data not shown).

The time-resolved data shown in Figs. 7 and 8 show some structure at times smaller than the onset time. We cannot rule out that this structure, which appears to persist despite statistical averaging, a ects our quantitative conclusions for the onset times and weak localization corrections. Since there is no such small-time structure in the weak localization data obtained by varying the eld

, we conclude that the small-time feature in the data of Figs. 7 and 8 m ust be a non-m agnetic-eld-dependent quantum correction (e.g., resulting from di raction at the contacts). The feature disappears quickly upon increasing the stochasticity parameter K.

The largest channel numbers in our simulations

FIG.8: W eak localization correction to re ection and transmission coe cients, obtained using Eq. (16). D ata shown are for K 10 and $_{\rm D}$ = 10. The number of realizations used to calculate the ensemble average is 20000.

FIG.9: Left: O nset time t_{on} obtained from the time-resolved weak localization correction G_{LR} . Right: Weak localization correction G_{LR} , togetherwith a t / exp($_{E} = _{D}$). D at a are taken with stochasticity parameter K uniform ly chosen between 10 and 11:5 (circles) and between 20 and 23 (squares), and for dwell times $_{D} = 5$ (solid) and $_{D} = 10$ (dashed).

N = 200 and N = 400 for the scaling method, with an average over 80 000 and 40 000 sam ples (for K 10), respectively | are sm aller than the largest channel num ber used in the simulations Ref. 21. The observed decrease of the weak localization correction is statistically significant and system atic, but sm all. We could not obtain su ciently accurate simulation data for higher num ber of channels. Increasing N at xed num erical cost in plies that the num ber of realizations in the average has to scale / N², so that the statistical error scales / N. Obtaining simulation data for N = 800 at the same num erical cost as our N = 200 data, would mean that only 5000 sam ples can be averaged over, increasing the error by a factor 4. At that point the statistical error becomes

FIG.10: T in e-resolved shot noise Fano factors for the open kicked rotator, with K = 10 and $_{\rm D}$ = 5. Left inset: O nset times, determ ined from the location of the maximum of timeresolved Fano factor as a function of the truncation time t₀. Right inset: Fano factor compared to a t / exp($_{\rm E}$ = $_{\rm D}$). Results for K 10 (circles), K 20 (squares), $_{\rm D}$ = 5 (solid lines), and $_{\rm D}$ = 10 (dashed lines) are depicted in the insets.

parable to the expected increm ental decrease of the weak localization data, and the simulation data loose statistical signi cance.

Shot noise. Figure 10 shows tim e-resolved data for the shot noise Fano factor F, taken for the one-kick model with stochasticity parameter K 10 and dwell time $_{\rm D}$ = 5. The statistical average was taken over 20 realizations only, which is su cient as the Fano factor is self-averaging for large channel num bers. A m ore quantitative analysis of the data for K 10 (circles), K 20 (squares), $_{\rm D}$ = 5 (solid lines), and $_{\rm D}$ = 10 (dashed lines) is presented in the insets. Onset times, determined from the maximum of the F (t_0) graphs, are shown in the left inset of Fig. 10, together with a linear t / E + const; using the Lyapunov exponents obtained from the corresponding classical map. The time of the maximum was de ned as onset tim e since it is problem atic to obtain reliable onset times using the de nition used previously. However, num erically obtained onset times for shot noise are signi cantly in pacted by the discreteness of the map's time evolution, and do not show a sm ooth linear increase with N over the range of channel num bers investigated in our simulations. The right inset of the gure shows values of the Fano factors for the lim it of large truncation times, together with ts / exp ($_{\rm E} = _{\rm D}$), with the Lyapunov exponents obtained from the corresponding classical map. We conclude that the rate of exponential suppression of shot noise upon increasing N is consistent with the rate of exponential suppression of weak localization.

Conductance uctuations. We performed timeresolved simulations for the variance of the relection from the left contact G_{LL} , the covariance of relection G_{LL} and transmission G_{LR} , and the covariance of relection

FIG. 11: The truncation time-dependence of varG_{LL}, cov (G_{LL};G_{LR}), and cov (G_{LL};G_{RR}) for the one-kick rotator. The dwell time is $_{\rm D}$ = 5, while K is chosen uniform by between 10 and 115. The corresponding time dependence given by random matrix theory is shown dashed. The short-time behavior is magnied in the inset.

tions from the left and right contacts. We have computed the variance of the conductance coe cient G_{LL}, as wellas the covariances cov (G_{LL};G_{LR}) and cov (G_{LL};G_{RR}) as a function of the truncation time t₀. Unitarity of the scattering matrix in plies that varG_{LL} = cov (G_{LL};G_{LR}) = cov (G_{LL};G_{RR}) if t₀ ! 1, but this equality does not hold for nite t₀. Our simulations were done for dwell times $_{\rm D}$ = 5 and 10, and for stochasticity parameters K between 10 and 11:5 and between 20 and 23. Results

FIG.12: Left: O nset time t_{on} obtained from the time-resolved conductance covariance data. R ight: C onductance covariance covariance cov (G_{LR};G_{LL}). D ata are taken with stochasticity parameter K uniform by chosen between 10 and 11:5 (squares) and between 20 and 23 (circles), and for dwell times _D = 5 (solid) and _D = 10 (dashed).

for $_{\rm D}$ = 5 and K 10, which are representative for all results obtained, are shown in Fig. 11. The number of realizations used for the averages shown here is 80000 for D = 5, except for the N = 800 data point, for which only 40 000 realizations were taken. The statistical error of the variances was estimated to be 10⁴. Onset times calculated from the time-resolved covariance of G $_{\rm LL}$ and G_{LR} are shown in Fig. 12, together with conductance covariances. The scatter of the data points in the right panel of F ig. 12 for the short dwell time $_{\rm D}$ = 5 is larger than our statistical error and reproducable. It is probably an artefact of the discrete time evolution of the map. (Note that sim ilar scatter exists for the weak localization data, although, in that case, it is obscured by the large system atic decrease of the weak localization correction upon increasing N .)

As can be seen from the left panel of Fig. 12, the onset time depend linearly on ln N: on $0:55\ln N + const:$ 0:38 ln N + const. for K for K 10 and on 20. However, the slopes are a factor 2:2 sm aller than for the weak localization data, both for K 10 and K 20. Further, the conductance variance (i.e., the large- t_0 lim it of the data shown in Fig. 11) shows a slight increase with increasing N . The total increase is less than 10% over the range of channel num bers considered in our simulations and falls within the statistical uncertainty of simulations reported in Refs. 9,18,22, where it was concluded that varG is independent of N. Simulations of conductance uctuations for the three-kick m odel slow a less than 10% decrease of varG for the sam e range of N , as well as on set times that increase signicantly slower with N than the onset times for weak localization in the three-kick model (data not shown).

C learly, the simulation data for conductance uctuations are qualitatively di erent from the simulation data for weak localization; they di er both with respect to the N -dependence of the onset times and the N -dependence of the magnitude of the quantum corrections. This contradicts the notion that the same interference processes (di usons and cooperons and their generalizations to ballistic system s) underly both weak localization and conductance uctuations, although one should note that there is no sem iclassical theory of the Ehrenfest-tim e dependence of conductance uctuations yet.

III. QUANTUM TRANSPORT THROUGH CHAOTIC CAVITIES:SEM ICLASSICAL THEORY

A sem iclassical theory for the Ehrenfest-time dependence of the weak localization correction in chaotic cavities was rst form ulated by A leiner and Larkin.² That theory predicts that the weak localization correction is suppressed / exp $(2_{\rm E} = D)$. However, the analysis of Ref. 2 does not account for all classical correlations: it neglects the notion that no quantum di raction takes place for electrons that spend less than a time $_{\rm E}$ in the cavity. In this section we show that accounting for all classical correlations gives a weak localization correction that still. depends exponentially on the Ehrenfest time, but with a di erent exponent: G / exp($_{\rm E} = _{\rm D}$). W hile a part of our calculations has already appeared elsew here,¹¹ this section includes a calculation of the full conductance m a-. This allow s to verify that unitarity is preserved. trix G As the possible loss of unitarity is known to be a problem in sem iclassical theories, it is important to demonstrate explicitly that the m ethod used here preserves probability.

The system under consideration is a ballistic cavity with chaotic classical dynamics. The cavity is twodimensional, and it is coupled to two electron reservoirs via contacts of width $d_{\!\rm L}\,$ and $d_{\!R}$, see F ig. 13. Ergodicity of the electron motion inside the dot is ensured by the condition d_L;d_R L. The cavity and the contacts are considered in the sem iclassical lim if $d_{L}k$; $d_{R}k$ 1, where k is the electron wavenum ber. Thus, one has the separation of length scales 1=k L or, equivalently, d_{I} ; d_{R} the separation of time scales (vk) 1 $_{\rm D}$, where erq v is the electron velocity, erg L=v the ergodic tim e, and D the dwell time. The latter can be expressed as

$$_{\rm D}^{1} = \frac{(d_{\rm L} + d_{\rm R})v}{A;}$$
 (21)

where A is the area of the cavity. W e also de ne

$$P_{R} = \frac{d_{R}}{d_{R} + d_{L}}; P_{L} = \frac{d_{L}}{d_{R} + d_{L}}$$
(22)

as the probabilities that an electron at a random point in the cavity will leave through the right and left contacts, respectively. Electron motion inside the cavity is assumed to be fully phase coherent and electron-electron interactions are neglected.

FIG.13: Schem atic picture of the ballistic chaotic cavity of size L. The cavity is attached to two leads, labeled \L" and $\backslash R$ ", and with width d_L and d_R , respectively. The contours C $_L^0$, C $_L$, and C $_R$ drawn in the leads are used for the calculation of transm ission and re ection coe cients, see the text.

The classicalm otion in the cavity is assumed to be fully chaotic (when closed), with a Lyapunov exponent . This exponent m easures the rate of divergence of close phase space points. Since this divergence is due to scattering from the curved walls of the cavity one can expect that

 $l=_{erg}$. We neglect uctuations in the Lyapunov exponent and assume that its value is uniform. This is done to simplify the calculation as much as possible and should not a ect the main physical conclusions as long as relevant times are much longer than $_{erg}$.

The Aleiner-Larkin formalism is based on a sem iclassical description of transport. Central objects in their theory are the non-oscillating parts of the product of an advanced and retarded G reen functions. The \di uson" is composed of combinations of orbits with them selves (known as the diagonal approximation in the sem iclassical community) while the \cooperon" is composed of orbits and their time reversal counterparts. The equation of motion for the di uson, neglecting quantum phenom ena, is the Liouville equation,

h

$$i! + \hat{L}_1^{I} D^{0} (!;1;2) = (1;2);$$
 (23)

where j $(j;R_j) = 1;2$ denotes the phase space coordinates, limited to the energy shell: R is the electron position while the angle represents is the direction of the electron's velocity v. The operator \hat{L}_1 is the Liouville operator, taken with respect to the coordinates $(_1;R_1)$. For a hard wall cavity, $\hat{L} = v$ (e=0R, with appropriate boundary conditions at the walls. The symbol

(1;2) denotes a delta function on the energy shell, that is, (1;2) 2 ($R_1 R_2$) ($_1 2$).

Quantum e ects are introduced by including a weak additional random quantum potential, treating it as a perturbation, and averaging over its realizations.² This random potential leads to two di erent e ects, which are expected in a quantum theory. The rst is a di usion in phase space, which m im ics the fact that quantum dynam ics cannot separate sm all phase space structures. The second e ect is 'quantum switching' between close phase space trajectories, which results in weak localization. The strength $_{\rm q}$ of these e ects is then set so that quantum corrections will appear after the correct time, the Ehrenfest time $_{\rm E}$. Phase space di usion m odi es the evolution equation for the leading order di uson as²

$$i! + \hat{L}_1 = q \frac{\hat{e}^2}{\hat{e}_1^2} D^0 (!;1;2) = (1;2):$$
 (24)

the strength $~_q$ of the phase space di usion term is estimated to be $^2~_q$ \prime $^2=\!kv.$ It is instructive to note that

this term, although small, breaks the time reversal invariance which is a property of both quantum mechanics and classical mechanics (in absence of a magnetic eld). In the presence of quantum di raction, the leading order cooperon, C^0 , also satis es Eq. (24).

In addition to the presence of the phase space di usion term in the evolution equation (24), quantum di raction leads to an quantum correction to the di uson: $D = D^0 + D$. This quantum correction is referred to as weak localization, because sim ilar quantum corrections are the precursor of Anderson localization in disordered system s. The weak localization correction for the di uson reads²

$$D(!;1;2) = D^{0}(!;1;2)\frac{C^{0}(!;2;2)}{2h} + \frac{C^{0}(!;1;1)}{2h}D^{0}(!;1;2) + \frac{C^{0}(!;1;2)}{2h}Z^{0}(!;1;3)D^{0}(!;3;2) 2i! \hat{L}_{3} + q\frac{\theta^{2}}{\theta^{2}}\frac{C^{0}(!;3;3)}{2h}; (25)$$

where $j = (j + R_j)$ denotes the time reversal of phase space point j and $m = m = 2 h^2$ is the density of states per unit area. In terms of classical trajectories, the weak localization correction D corresponds to a conguration as shown in Fig. 1a: D is the correction to the product of a retarded and advanced G reen function arising from the combination of a trajectory that intersects itself at a small angle and a trajectory that avoids intersecting itself.^{2,40} If the intersection angle is su ciently small, such a pair of trajectories has strongly correlated actions, resulting in a net quantum correction to the di uson even after ensemble averaging. The pairs of trajectories before and after the 'interference region' are represented by the leading-order di usons D⁰ in Eq. (25), whereas the trajectories in the closed loop | an orbit conjugate to its time-reversed counterpart | are represented by the leading order cooperon C⁰.

In order to calculate the weak localization correction to the conductance, the dot's conductance coe cients G $_{\rm LL}$ and G $_{\rm R\,L}$ are expressed in terms of the di uson D ,

$$G_{RL} = 2 h \sqrt[q]{2} \frac{Z}{C_{L}^{0}} \frac{d_{L}}{d_{L}^{0}} = 2 \frac{d_{1}}{2} \cos(L_{1}) \frac{Z}{C_{R}} \frac{Z}{d_{2}} \frac{Z}{d_{2}} \cos(R_{1}) \frac{d_{2}}{d_{2}} \cos(R_{1}) \frac{d_{2}}{d_{2}} (26)$$

and

$$G_{LL} = 2 h v dl_{1} \qquad \begin{bmatrix} Z & Z & U & U \\ U & U & U \\ C & U & U$$

Here C_L , C_R , and C_L^0 are smooth contours following a cross section of the contacts, see Fig. 13. The contour C_L^0 is taken a small amount further away from the cavity than the contour C_L , see Fig. 13. The angles $_L$ and $_R$ denote the direction of the outward-pointing norm alto C_L , C_R , whereas the angle $_L^0$ represents the direction of the inward-pointing norm alto C_L , C_R , whereas the angle $_L^0$ represents the direction of the inward-pointing norm alto C_L . Since we consider DC transport, the frequency ! has been set to zero. We refer to the Appendix for a derivation. Sim ilar expressions, but with an ambiguity in the precise de nitions of the integrals over the lead cross sections, were derived by Takane and N akam ura.¹⁶

The leading order $\$ assical" transmission and rejection coecients are found by substituting D⁰ for D. A ssuming that dynamics in the cavity is ergodic for all relevant time scales, one $nds^{2,16}$

$$G_{RL}^{0} = G_{LL}^{0} = \frac{2 h A}{D} P_{L} P_{R};$$
 (28)

where the escape probabilities to the left and right leads were de ned in Eq. (22) above.

The weak localization correction to the conductance coe cients G $_{RL}$ and G $_{LL}$ is obtained by substituting Eq. (25), for the weak localization correction D of the di uson, into Eqs. (26) and (27). We rst consider the weak localization

connection to G_{RL} . The set two terms in (25) contain paths which leave the dot at the point of entry, and hence these do not contribute to the transmission. Hence

$$G_{RL} = \sqrt[4]{2} \sum_{\substack{0 \\ L \\ m}}^{Z} \frac{d_{1}}{d_{1}} = 2 \frac{d_{1}}{2} \cos(\frac{0}{L} - 1) \frac{d_{2}}{d_{1}} \cos(\frac{0}{L} - 1) \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \cos(\frac{0}{L} - 1) \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \cos(\frac{0}{L} - 1) \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{2}} \cos(\frac{1}{R} - 2) \frac{d_{1}}{d_{2}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{2}} \frac{d_{1}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{1}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{1}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{1}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{1}}{d_{1}} \frac{d_{2}}{d_{1}} \frac{d_{1}}{d_{1}} \frac{d_{1}}{d_$$

The phase space point 3 can be viewed as the center of the 'interference region' as depicted in Fig. 1a. The two di usons and the cooperon head into opposite directions in phase space, so that they will sample di erent parts of phase space along the trajectory. Thus, one can treat them as statistically uncorrelated.²

Both the cooperon and the product of di usons in Eq. (29) exhibit non-trivial correlations since the returning path is strongly correlated with the outgoing one, cf. Fig. 1a. In order to take into account these correlations one should exam ine what is meant by the phase space points 3 and 3 in Eq. (29). By virtue of the phase-space diusion term in the evolution equation for the leading order di uson, e ectively, the points 3 and 3 do not need to be exactly time reversed phase space points, since quantum mechanics allows for a nite phase space uncertainty. An intuitive way to calculate the correlations between 3 and 3 was shown by Vavilov and Larkin.⁴¹ Instead of using the di usion in phase space, Vavilov and Larkin average over a range of initial phase space points near 3 and nalphase space points near 3. They show that the e ect of the phase space di usion is equivalent to such averaging (up to logarithm ic corrections) if the 'size' of phase space area near 3 and 3 scales as k $^{1=2}$. [To be precise, the range of coordinates R in the average is $(L=k)^{1=2}$, whereas the angular range is $(Lk)^{1=2}$.] W e adopt the procedure of Vavilov and Larkin and consider an average over phase space points 3^0 and 3^{00} that are within a distance of order k $^{1=2}$ of the phase space point 3. W e can then follow the classical orbits which start at the points 3^0 , 3^{00} . The phase space distance between these trajectories will diverge exponentially due to the chaotic dynam ics. Since the trajectories start from phase space points at a distance $k^{1=2}$, it will take a time E=2 to reach a phase space distance of order L. Once the phase space distance between the trajectories is large enough they can be considered as totally uncorrelated. At this point, ergodic dynam ics can be assum ed. The loss of correlations happens on a time scale of 1= around the time $_{\rm E}$ in the parameter regime where the E = 2. Since 1 =Ehrenfest time a ects quantum transport, we can view this process as e ectively instantaneous.

Let us rst consider the cooperon in Eq. (29). As a result of the phase space correlations described above, one cannot close the orbit from 3^0 to 3^{00} for short times. In order to make thism ore quantitative, we denote by t_j the time it takes for the classical orbit starting at phase space point j to leave the cavity through one of the two openings. Then, if $t_3 < {}_E = 2$ we nd C⁰ (3;3) = C⁰ (3⁰;3⁰) = 0. On the other hand, if $t_3 > {}_E = 2$ we can propagate the phase space point 3⁰ for a time ${}_E = 2$ and reach phase space point 4. Sim ilarly, we can propagate 3⁰⁰ backward in time and nd, toward the phase space point 5. This leads to

$$C^{0}(3^{00};3^{0})' = \begin{array}{c} 0 & \text{if } t_{3} < E = 2; \\ C^{0}(5;4) & \text{if } t_{3} > E = 2: \end{array}$$

W hen the phase space points 3^0 and 3^{00} are averaged over, the cooperon will have contributions from various phase space points 5;4, which are their distant past (or future). The points 4 and 5 can be taken to be uncorrelated and sample the phase space with uniform probability. Since the phase space point 3 is eventually integrated over, there will be contributions from a sizable fraction of phase space. Thus, we approxim ate the average contribution to the cooperon by replacing C^0 (5;4) by its average value $_{\rm D}$ =A. This leads to

$$C^{0}(3;3) = \frac{D}{A} (t_{3} = 2);$$
 (30)

where (x) = 1 if x > 0 and 0 otherwise.

W e address the product of two di usons in Eq. (29) by considering the integral

$$I(3) = \sqrt[9]{2} \frac{Z}{dl_{1}} \frac{Z}{dl_{2}} \frac{d_{1}}{dl_{2}} \cos(\frac{0}{L})$$

$$Z = \frac{Z}{dl_{2}} \frac{d_{2}}{dl_{2}} \frac{d_{2}}{dl_{2}} \cos(\frac{0}{L})$$

$$Z = \frac{Z}{dl_{2}} \frac{d_{2}}{dl_{2}} \cos(\frac{1}{L})$$

A gain, the integration over phase space points 3 and 3 is replaced by an average over phase space points 3^0 and 3^{00} within a distance of order $(L=k)^{1=2}$ from 3. Since the di uson connects the phase space points 3^0 and 3^{00} with points at two di errent contacts, the product of di usons must be zero if $t_3 < E=2$ where, as before, t_3 is the time it takes for the orbit at phase space point 3 to leave the system. For larger t_3 we may, again, assume ergodicity, so that we nd, after averaging over 3^0 and 3^{00} ,

$$I(3) = P_R P_L$$
 (t₃ _ _ _ _ =2):

Combining results, we nd

$$G_{RL} = P_{R}P_{L}\frac{D}{A} d3 (t_{3} = 2)\hat{L}_{3} (t_{3} = 2):$$

(31)

The Liouville operator in Eq. (31) m easures the rate of ow of probability density out of the integration range of the phase space variable 3.² The boundary of the integration range is composed of the lead phase space points propagated backward for a time $t_E = 2$. This leaves only a fraction exp($\frac{E}{2}$) of the size of the boundary at the lead. To estimate the integral we assume that each outgoing direction is equally likely to be in the system when propagated backward. How ever, only points which also have $t_3 > E = 2$ will have a non-vanishing cooperon, leading to an additional factor of exp($\frac{E}{2}$). Collecting contributions from both leads, we nd

$$G_{RL} = P_{R}P_{L}e^{E^{-D}}$$
: (32)

It is of interest to compute also the weak localization correction $G_{\rm LL}$. This will allow to check that probability is conserved. The calculation is sim ilar to that of the $G_{\rm RL}$, with two important di erences. The rst di erence is that the weak localization correction of relation is composed from two parts. In addition to the third term in Eq. (25), there is a contribution from the second term in Eq. (25). We write these two parts as $G_{\rm LL}^{(1)}$ and $G_{\rm LL}^{(2)}$, respectively, and calculate them separately. Substitution of the third term in Eq. (25) into Eq. (25) into Eq. (27) gives

$$G_{LL}^{(1)} = \sqrt{2} \int_{C_{L}^{0}}^{Z} dl_{1} = 2 \frac{d_{1}}{2} \cos\left(\frac{0}{L}\right) \int_{C_{L}}^{Z} dl_{2} \int_{C_{L}^{0}}^{Z} dl_{2} \frac{d_{1}}{dl_{2}} \cos\left(\frac{0}{L}\right) \int_{C_{L}^{0}}^{Z} dl_{2} \frac{d_{2}}{dl_{2}} \cos\left(\frac{1}{L}\right) \int_{C_{L}^{0}}^{Z} dl_{2} \frac{d_{2}}{dl_{2}} \frac{d_{2}}{dl_{2}} \cos\left(\frac{1}{L}\right) \int_{C_{L}^{0}}^{Z} dl_{2} \frac{d_{2}}{dl_{2}} \frac{d_{2}}{dl_{2}} \cos\left(\frac{1}{L}\right) \int_{C_{L}^{0}}^{Z} dl_{2} \frac{d_{2}}{dl_{2}} \frac{d_{$$

The product of the two di usons can be assumed to be uncorrelated with the cooperon. The calculation of the cooperon proceeds as for the transmission calculation. However, the behavior of the product of the di usons contributing to re ection di er from that of the di usons contributing to transmission. To see that, again consider the integral

$$I(3) = \sqrt[4]{2} \sum_{L=2}^{Z} \frac{d_{L}}{dl_{L}} \frac{d_{L}}{dl_{L}} = 2 \frac{d_{L}}{2} \cos(\frac{d_{L}}{dl_{L}} - 1) \frac{d_{L}}{dl_{L}} \frac{d_{L}}{dl_{L}} = 2 \frac{d_{L}}{2} \cos(\frac{d_{L}}{dl_{L}} - 2) D^{0}(2;3) D^{0}(3;1):$$

If $t_3 > {}_E = 2$ both di usons becom e uncorrelated before leaving the system and the average value of this integral is therefore P_L^2 . However, if $t_3 < {}_E = 2$ both di usons will exit the dot through the same lead, and one nds $I = P_L$. Hence,

$$I = P_{L} \text{ if } t_{3} < E = 2;$$

$$P_{L}^{2} \text{ if } t_{3} > E = 2:$$

This is the second di erence between the calculations of $G_{R\,L}$ and $~G_{L\,L}$. We then ~nd

$$G_{LL}^{(1)} = P_L e^{E^{-2} D} (1 e^{E^{-2} D}) P_L^2 e^{E^{-1} D}$$
; (34)

The contribution $G_{LL}^{(2)}$ is obtained by substituting the second term in the right hand side of Eq. (25) into Eq. (27). The lead integral over 2 can be calculated, resulting in

$$G_{LL}^{(2)} = v dl_{1} dl_{1} = P_{L}e^{E^{-2}D};$$
(35)

C om bining Eqs. (35) and (34), one nds $G_{LL} = G_{LL}^{(1)} + G_{LL}^{(2)} = G_{RL}$, as expected.

The result (32) shows that, according to the sem iclassical theory, the weak localization correction to transm ission is suppressed exponentially. However, the exponent we nd is di erent from that of Ref. 2, where it is reported that $G_{RL} = P_L P_R \exp(2_E = D)$. The reason for the di erence with R ef. 2 is that our calculation obeys the classical correlations following from the separation of phase space into a classical and quantum ' part, corresponding to (classical) trajectories of length smaller or larger than E, respectively. Quantum di raction does not involve the classical' part of phase space. Calculating the cooperon and the product of di uson propagators assum ing ergodic dynam ics in the 'quantum ' part of phase space only increases the weak localization correction G by a factor exp ($_{\rm E} = _{\rm D}$) with respect to the calculation of Ref. 2. The reason that G remains exponentially small

but with exponent exp($_{E} = _{D}$), not exp($_{2E} = _{D}$) is that, according to the sem iclassical theory, weak localization requires a m inim alpath length of 2_{E} v. The fraction of quantum ' trajectories that rem ain inside the cavity during the time period 2_{E} is exponentially sm all, / exp($_{E} = _{D}$), hence the exponentially sm all weak localization correction if $_{E}$ ______ D.

Sofar we have considered the weak localization correction to the transmission. W hat about other quan-

tum interference e ects, such as the transmission uctuations? Takane and Nakamura have extended the sem iclassical theory of A leiner and Larkin to the conductance variance varG, but for the lim it $_{\rm E}$! 0 only.¹⁷ They found varG = $2(P_L P_R)^2$, in agreement with predictions from random matrix theory.⁴ Just as the sem iclassical theory for the weak localization correction G_{RL} was simpler than the sem iclassical theory for $G_{I,I}$ (see above), the sem iclassical theory of transm ission uctuations takes its simplest form if applied to the covariance of relection from the right contact G_{RR} and relection from the left contact $G_{\,{\rm L\,L}}$. Of course, unitarity in plies varG = $cov (G_{LL}; G_{RR})$. In Ref. 17, only one contribution to the conductance covariance $cov (G_{LL}; G_{RR})$ was considered. This contribution corresponds to the four trajectories shown in Fig. 1b. For these four trajectories, a m in in all dwell time 2 $_{\rm E}$ is required: classical trajectories originating from each of the openings need to diverge and reunite, each of which takes a time $_{\rm E}$. Hence, follow ing the same phase space argum ents as for the weak localization correction, we anticipate that their contribution to the conductance uctuations depends on the Ehrenfest tim es as

$$[cov (G_{LL};G_{RR})]^{1=2} = [varG]^{1=2} / e^{E^{-D}}$$

if E^{-D} (36)

However, there may be contributions to the conductance uctuations other than that of Fig. 1b. (This possibility can not be excluded on the basis of R ef.17.) For example, there may be trajectories that involve small-angle intersections of three trajectories at the same point.^{42,43} W hile it is not expected that the inclusion of such trajectories undo the suppression of the conductance uctuations in the lim it $_{\rm E}$ $_{\rm D}$, they may have a non-negligible contribution for $_{\rm E}$ $_{\rm D}$.

A nalnote about the results presented in this section: In the calculation performed in this section we have replaced dynam ical functions by their averages. For exam ple, the probability that a wave packet will exit through a given lead is (alm ost) 1 or 0 for short enough tim es, depending on the classical dynam ics, not P_L or P_R . Thus, we have actually estim ated the ensemble average of the weak localization correction. One can expect that if a system is close to the classical lim it there will be more uctuations in the values of di usons and cooperons. This may lead to large deviations of the weak localization correction from that of system swith smallEhrenfest times, and to large classical conductance uctuations.²² In order to describe these uctuations quantitatively, one needs a sam ple-specic theory for the dynam ics of the diffuson, which covers the times of order $_{\rm E}$ exactly. While this is an important theoretical problem, it is beyond the scope of this paper, and should not a ect the eventual exponential suppression of quantum interference phenom ena for large Ehrenfest tim es.

In Sec. II, we reported results of num erical simulations for weak localization, conductance uctuations, and shot noise of the open quantum kicked rotator. The num erical simulations for weak localization and shot noise are consistent with an exponential suppression / exp $(E_{\rm E} = D_{\rm D})$, in quantitative agreem ent with the sem iclassical theory of Sec. III. The num erical simulations for conductance uctuations show a sm all increase with increasing E hrenfest time, not inconsistent with previous simulation data reported in the literature.9,18,22 Our simulations also give information on the minimal time at which quantum effects occur. For weak localization and shot noise, these times are 2 $_{\rm E}$ and $_{\rm E}$, respectively, consistent with sem iclassical theory. For conductance uctuations, the onset time is less than half the onset time of weak localization. (Note that it is possible that som e contribution for weak localization in relection may appear after a time of $_{\rm E}$.)

In order to explain the num erical simulations of shot noise, weak localization, and universal conductance uctuations, the authors of Refs. 8,9,18,22 proposed a phenom enological alternative to the standard sem iclassical theory, referred to as 'e ective random matrix theory'. Guiding principle for the e ective random matrix theory is that quantum di raction takes place between trajectories with dwell times larger than $_{\rm E}$ only; trajectories with dwell time shorter than $_{\rm E}$ build scattering states with transmission (exponentially close to) 0 or 1 and do not contribute to shot noise, weak localization, or universal conductance uctuations. The importance of guantum ' trajectories is described by an elective number of quantum channels'N_q N exp ($_{\rm E} = _{\rm D}$). Following Silvestrov et al,⁴⁴ it was then proposed that the scattering of 'quantum channels' is described by random matrix theory as long as N_q 1. The condition N_q 1 is generically met, even if $_{\rm E}$ D •

The e ective random matrix theory not only correctly predicts the suppression of the ensemble-averaged shot noise at large Ehrenfest times shot noise is proportional to the number of channels N , which is replaced by $N_q = N \exp(E_E = D)$ in the elective random matrix theory |, it also describes sam ple-speci c deviations from the ensemble average that arise from the classical dynam ics.8 The e ective random matrix also has had remarkable success explaining other observables that are proportional to the channel num ber N , such as the density of transmission eigenvalues,¹⁰ as well as the density of states in a chaotic cavity coupled to a superconductor.⁴⁴ On the other hand, quantum -interference e ects, such as weak localization and conductance uctuations are independent of N, and, hence, are predicted to be independent of the Ehrenfest time. Thus, for weak localization, the e ective random matrix theory di ers from the sem iclassical theory, which predicts a suppression $/ \exp(_{\rm E} = _{\rm D}).$

The e ective random matrix theory and the sem iclassical description of transport not only disagree regarding the magnitude of the weak localization correction to the conductance, they also disagree with regard to the minimal time required for quantum interference e ects to occur. In the sem iclassical theory, quantum interference requires a minimal wavepacket to be split and reunited, which takes a minimal time 2 $_{\rm E}$. This is in contrast to the e ective random matrix theory, where quantum interference is fully established already after a time $_{\rm E}$. Interestingly, there is no di erence between sem iclassics and e ective random matrix theory for shot noise: Not being a quantum interference ect, shot noise only requires wavepackets to be split, which happens after a time $_{\rm E}$ in both theories.

These two di erences between the sem iclassical theory for weak localization and the elective random matrix theory are not unrelated. Both theories are consistent with a fully classical description of electron dynamics for the rst time interval of length $_{\rm E}$ after the electron has entered the cavity. Di erences between the two theories appear for electrons that escape from the cavity in the second time interval of length $_{\rm E}$ (i.e., for times between $_{\rm E}$ and 2 $_{\rm E}$). In the sem iclassical theory, electrons that escape during this interval behave quantum mechanically but do not contribute to weak localization. A sexplained in Sec. III, the escape of electrons between $_{\rm E}$ and 2 $_{\rm E}$ is responsible for the suppression of weak localization with exponent exp $(E_{\rm E} = D_{\rm D})$ in the sem iclassical theory. In the e ective random matrix theory, weak localization sets in as soon as the classical description fails, one Ehrenfest tim e after the electron enters the cavity; there is no tim e interval in which electron dynam ics is neither fully classical nor described by random matrix theory.

A 'm icroscopic theory' supporting the elective random m atrix theory and its prediction of Ehrenfest-time independent weak localization and conductance uctuations appeared recently.⁴⁵ This theory is based on the assum ption that electron dynamics in the quantum trajectories (i.e., trajectories with dwell times larger than $_{\rm E}$) is fully ergodic, with fully established quantum interference corrections. Such an assumption violates the sem iclassical picture of weak localization, in which the quantum correction only appears after a time 2 $_{\rm E}$. Hence, a theory which tries to justify the elective random matrix theory must provide an entirely new sem iclassicalm odel for weak localization, in which the quantum correction appears after one Ehrenfest time only.

A lthough, at present, there is no theory that explains all simulation data, we can conclude that our timeresolved simulation data for the quantum interference corrections to the conductance are not consistent with the elective random matrix theory. First, because the elective random matrix theory predicts onset time $_{\rm E}$ for weak localization, as well as an Ehrenfest-time independent weak localization correction, both of which are ruled out by our simulations. Second, because simulation results for weak localization and conductance uctuations are qualitatively dilerent, whereas the ble ective random matrix theory' predicts equal onset times and EhrenfestO f course, the question why num erical simulations for weak localization and conductance uctuations in the open quantum kicked rotator are qualitatively di erent remains. Clearly, this question can not receive a nal answer as long as there is no sem iclassical theory for the Ehrenfest-time dependence of conductance uctuations. G iven the di culty of obtaining accurate num erical results in the regime $_{\rm E}$ _ _ _ _ , such a sem iclassical theory needs to include the parameter range $_{\rm E}$ _ _ _ _ _ _ _ _ _ _ _ _ _ _ _ _ if a valid com parison with the num erical simulations is to be made.

A cknow ledgm ents

W e would like to thank C.Beenakker, S.F ishm an, H. Schom erus, P.Silvestrov, and D.Ullm o for discussions. This work was supported by the NSF under grant no. DMR 0334499 and by the Packard Foundation.

APPENDIX A:TRANSM ISSION AND REFLECTION IN TERMS OF DIFFUSONS

In this Appendix the transmission and rejection through a quantum dot are derived in terms of lead integrals of a di uson. Sim ilar expressions were derived previously by Takane and Nakam ura.¹⁶ However, their expressions are ambiguous with respect to the exact locations of the cross sections in the leads. In our approach, all ambiguities are resolved.

To calculate the total transmission and rejection in terms of di usons, it is useful to obtain expressions for scattering matrix elements using the retarded G reen function of the cavity. Exact expressions of this type were derived in Refs. 46,47. The leads have a uniform cross section, so that the lead wavefunction can be decomposed into free waves along the lead (denoted by x coordinates) and a basis of transverse wavefunctions $_{a}$ (y). The same decomposition can also be used for the retarded G reen function (at the Fermi energy), and one de nes

$$G^{+}(r_{1};r_{2}) = \int_{mn}^{A} G_{mn}^{+}(x_{1};x_{2}) m(y_{1}) n(y_{2}); \quad (A1)$$

for coordinates r_1 and r_2 in the leads. W e use the convention that di erent leads are assigned di erent m odes, so that Eq. (A1) remains m eaningful if r_1 and r_2 are in di erent leads.

Using the asymptotics of G^+ and of the scattering states, the G reen function in the leads can be written in terms of scattering matrix elements $S_{m\,n}$. One nds^{46}

$$G_{m n}^{+}(x_{1};x_{2}) = \frac{i}{v_{n}} m_{n}e^{ik_{n}(x_{1} + x_{2})}$$

$$r \frac{r}{k_{n}}e^{ik_{n}x_{2} - ik_{m}x_{1}}; \quad (A2)$$

for $x_1 > x_2$ with $x_{1,2}$ in the left lead, and to

$$G_{m n}^{+}(x_{1};x_{2}) = \frac{i}{v_{n}}S_{m n}^{r} \frac{k_{n}}{k_{m}}e^{ik_{m}x_{1} - ik_{n}x_{2}}; \quad (A3)$$

for x_1 in the right lead while x_2 is in the left lead. (In the following we use units where h = 1.) For the following discussion it is in portant to emphasize the condition $x_1 > x_2$, which appears when both x_1 and x_2 are in the same lead. One of the steps in the derivation of Eq. (A2) involves an integral over a nite domain (bounded by the cross-section $x = x_2$), where the integrand is proportional to $(n_1 \quad p)$. This integral will give di erent results depending whether r_1 is in the domain of integration $(x_1 > x_2)$ or not $(x_1 < x_2)$. This leads to the inequality in Eq. (A2). Later, when we write $G_{m n}^+$ in terms of cross section integrals, two di erent cross sections, at x_1 and x_2 , are obtained.

To compute the conductance coe cients G $_{\rm LL}$ and G $_{\rm LR}$, the absolute value squared of the matrix elements is needed. It can be expressed in terms of G reen function with the help of

The conductance coe cients G $_{LL}$ and G $_{LR}$ are then calculated using Eq. (4). One can use Eq. (A 4) to simplify the sum m ations, since the lead m odes enter into $G_{m n}^{+}$ via cross section integrals over the leads. One then uses

$$X^{N}$$

_n (y₁) _n (y₄) '_F (y₁ y₄): (A 5)

Replacing this approximate nite width delta function by an exact one leads, after a straightforward calculation, to

$$G_{RL} = \frac{1}{4m^{2}} \sum_{C_{R}}^{Z} dy_{1} \sum_{C_{L}^{0}}^{Q} dy_{2} \frac{\theta}{\theta x_{1}} \frac{\theta}{\theta x_{4}}$$
$$\frac{\theta}{\theta x_{2}} \frac{\theta}{\theta x_{3}} G^{+} (r_{1}; r_{2}) G^{+} (r_{4}; r_{3}) \sum_{\substack{r_{1} = r_{4} \\ r_{2} = r_{3}}}^{r_{1} = r_{4}} (A 6)$$
$$1 \sum_{r_{2} = r_{3}}^{Z} \theta = \theta$$

$$\frac{4m^{2}}{4m^{2}} = \frac{4m^{2}}{c_{L}} = \frac{4m^{2}}{c_{L}} = \frac{4m^{2}}{c_{L}} = \frac{4m^{2}}{c_{L}} = \frac{6m^{2}}{c_{L}} = \frac{6m^{2}}$$

This expressions di er from those in Ref.16 in that the integrals for the re ection are along separate cross sections, with the cross section C_L closer to the cavity than C_L^0 .

O n each of the cross sections there are two points which are alm ost identified: r_1 ' r_4 and r_2 ' r_3 . Therefore, it is natural the use the following Fourier transform ^{2,16}

$$G^{+}(\mathbf{r}_{1};\mathbf{r}_{2})G(\mathbf{r}_{3};\mathbf{r}_{4}) = \frac{Z}{\frac{dp_{1}}{(2)^{2}}} \frac{dp_{2}}{\frac{dp_{2}}{(2)^{2}}} e^{ip_{1}(\mathbf{r}_{1} + \mathbf{r}_{4})}$$
$$e^{ip_{2}(\mathbf{r}_{3} + \mathbf{r}_{2})}K^{D}(p_{1};\mathbf{R}_{1};p_{2};\mathbf{R}_{2}); \quad (A8)$$

where $R_1 = (r_1 + r_4)=2$ and $R_2 = (r_2 + r_3)=2$. Note that R_1 and R_2 are on the cross sections of the lead. Energy conservation can be used to sim plify this probability density further. This is done by densing

$$K^{D}(p_{1};R_{1};p_{2};R_{2}) = \frac{2}{2m} E_{F} \frac{p_{1}^{2}}{2m} E_{F} \frac{p_{2}^{2}}{2m}$$
$$D(m;R_{1};n_{2};R_{2}): (A.9)$$

Substitution of (A 8) and (A 9) in (A 6) will lead to the expressions for G_{RL} and G_{LL} in terms of the di uson. The calculation is straightforward. Some care is needed only when one determ ines the boundary conditions. For G_{RL} , only di usions that go into the cavity can get from the left lead into the right lead. These di usons can arrive to the right lead only if they originate from the cavity. These considerations result in the Theta functions in Eq. (26). The calculation for G_{LL} is very sim ilar. The only di erence is that both incoming and outgoing di usons will cross the inner (C_L) cross section. However, all the incoming probability ux from C_L^0 must cross C_L . This incoming ux just cancels the N_L factor in (A 7). The remaining contribution results in Eq. (27).
