Abstract. – In the conventional theory of hopping transport the positions of localized electronic states are assumed to be fixed, and thermal fluctuations of atoms enter the theory only through the notion of phonons. On the other hand, in 1D and 2D lattices, where fluctuations prevent formation of long-range order, the motion of atoms has the character of the large scale diffusion. In this case the picture of static localized sites may be inadequate. We argue that for a certain range of parameters, hopping of charge carriers among localization sites in a network of 1D chains is a much slower process than diffusion of the sites themselves. Then the carriers move through the network transported along the chains by mobile localization sites jumping occasionally between the chains. This mechanism may result in temperature independent mobility and frequency dependence similar to that for conventional hopping.

Introduction. – Systems consisting of weakly coupled one-dimensional (1D) chains are ubiquitous and important. Anisotropic organic solids, polymers, columnar liquid crystals are just a few examples of quasi 1D systems important for applications. Biomaterials like DNA and proteins in many respects behave as topologically 1D systems. Because of structural and dynamic disorder, the charge transport in these materials is often due to incoherent phonon-assisted hopping of charge carriers between localized sites. Most theoretical models of hopping transport in quasi-1D systems predict a strong temperature dependence for the carrier mobility of the form $\mu \sim e^{-(T_0/T)^\alpha}$ with $\alpha \leq 1$ for variable-range hopping near the Fermi level and $\alpha = 2$ for Gaussian energy distribution of hopping sites. Although these predictions are often consistent with experiment, there are a growing number of experimental findings, mostly in soft matter systems, which are difficult to explain within conventional models of thermally-activated electron hopping. One such puzzle is temperature-independent mobility (TIM). First encountered in anisotropic organic crystals of polyacenes [1], TIM has been later observed in some other molecular crystals [2], columnar liquid crystals [3], and conjugated polymers [4]. Discussion of possible mechanisms of TIM has recently caught interdisciplinary attention after a very weak temperature dependence was reported for electron conductivity along the DNA double helix [5].

Because of the Einstein relation $\mu = eD/k_B T$, TIM implies that the diffusion coefficient D increases linearly with temperature. Such behavior is difficult to explain within conventional hopping models with the Miller-Abrahams expression for jump rates which depends

exponentially on temperature $W \sim \exp(-\Delta\epsilon/k_B T)$ for jumps upward in energy $\Delta\epsilon > 0$. A non-activated temperature dependence of W may under certain conditions be responsible for TIM. For weak electron-lattice coupling and temperature much higher than the maximal phonon energy, transition rates for optical-phonon-assisted hopping depend linearly on T [6]. Then the diffusion coefficient $D \sim W$ is proportional to the temperature, and the mobility $\mu = eD/k_B T$ is temperature independent. Although this argument may be consistently implemented for polyacenes [7], it can hardly be a general explanation of TIM. In fact, in liquid crystals, DNA, and some organic semiconductors TIM is usually observed below a certain temperature $T < T_c$, while an activated temperature dependence develops usually at $T > T_c$. Clearly, the above reasoning can not account for such a crossover.

Another feature of the systems exhibiting TIM is revealed by alternating current measurements. For relatively high frequencies the mobility typically increases as a power of frequency, $\mu(\omega) \sim \omega^s$ with $0 < s < 1$, while for low ω the mobility is frequency independent. This behavior is characteristic for the hopping mechanism, which therefore can account for the frequency dependence but apparently inconsistent with TIM.

It was suggested recently by many authors that the conflict may be resolved taking into account dynamic disorder, i.e. temporal fluctuations of the hopping distance and/or potential barrier. It was found that dynamic disorder can suppress the exponential temperature dependence in a limited temperature range [8].

In this Letter we consider a model of fluctuation driven transport where thermal fluctuations not only supply carriers with energy to jump (as in phonon-assisted hopping) or modify hopping rate parameters (as in models with dynamic disorder), but result in large scale diffusion of localization sites. Unlike 3D crystals, where atoms are always close to their equilibrium positions, the motion of atoms in 1D and 2D lattices may be to a large extent delocalized [9]. Let q_i is a displacement of the i th atom in a 1D harmonic chain with, for instance, fixed ends. All atoms have the same mass m , the harmonic force constant is k , so the highest oscillation mode has the frequency $2\omega_0$, with $\omega_0 = \sqrt{k/m}$. Using a normal mode transformation one can show (see for instance [10]) that for finite temperature T the mean square displacement (MSD) of an atom is proportional to its distance from the chain's end, and that the relative displacement of two atoms linearly increases with their separation,

$$\langle q_i^2 \rangle = \frac{k_B T}{m\omega_0^2} i, \quad \langle (q_i - q_{i+j})^2 \rangle = \frac{k_B T}{m\omega_0^2} j. \quad (1)$$

Because thermal deviations from periodic structure in one dimension is cumulative with distance, those atoms far from the ends of a long chain might vibrate over distances substantially longer than the equilibrium lattice spacing [9, 11]. In the infinite chain the motion of atoms is unbounded and has a diffusive character on a long time scale: although the relative displacement of two neighboring atoms is small, their MSDs diverge linearly in time. Because of loss of long-range order (Landau-Peierls instability), long chains in many respects behave more like liquids than crystals [11, 12], and are often referred to as 1D harmonic liquids. The lack of long-range correlations is manifested in diffuse x-ray and neutron scattering, which was observed in a number of linear-chain compounds [13]. Well-known example is columnar liquid crystals consisting of stacks of plate-like molecules arranged on a regular 2D lattice. Spectroscopy studies reveal liquid-like correlations in the direction along the columns. These systems, which often exhibit TIM [3], are essentially 2D lattices of 1D liquid columns [14]. Another example is polymers. In recent experiments with DNA coils the large-scale Brownian motion of monomers was directly measured for both semiflexible and flexible polymers [15].

Divergence of the atomic MSD in low-dimensional lattices is known to have important consequences for phase transitions, but we are unaware of any study of its implications for

carrier transport. In this Letter we consider effects of finite mobility of localized sites in a system of parallel chains neglecting chains flexibility, anharmonicity, quantum effects, etc. Although oversimplified, the model demonstrates clearly that a finite mobility of localized sites may result in TIM with a crossover to activated transport at high temperature, and also in frequency dependence similar to that for conventional electron hopping.

Let us assume for simplicity that each atom in a chain is associated with a localization site for charge carriers, and that only carrier jumps between near-neighbor atoms are important for hopping along the chain. The properties of phonon-assisted hopping in a static lattice depends on the type of disorder. To be specific, we shall assume the random energy model (known also as Gaussian disorder model) in which energy levels of sites are not correlated and characterized by a Gaussian distribution $g(\epsilon) \sim \exp\left(-\frac{\epsilon^2}{2\epsilon_0^2}\right)$. For this model, which is believed to be relevant to variety of organic conductors, the diffusion coefficient for nearest-neighbor hopping D_h has the form [16, 17]

$$D_h = \frac{a^2}{2} \nu e^{-a/L} e^{-(\epsilon_0/k_B T)^2}, \quad (2)$$

where a is the lattice spacing, L is the localization length of the carrier wave function, and ν is an attempt frequency. The exponential temperature dependence of (2) suggests that at low T hopping of carriers on a static lattice may be a much slower process than diffusion of atoms in the chain. Under these circumstances the carriers are transported along the chain by mobile localization sites while transport in the perpendicular direction is due to carrier hopping between neighboring chains. We shall discuss the possibility and some properties of this mechanism, referring to it as hitchhiking hopping, using two simple approximations.

Independent chains. – On a time scale $t \gg \omega_0^{-1}$ the motion of a tagged atom in an isolated infinite harmonic chain is diffusive, that is the MSD of the atom increases linearly with time, $\langle \Delta q^2(t) \rangle = \langle [q(t) - q(0)]^2 \rangle = 2D_a t$. The velocity correlation function $C(t) = \langle v(t)v(0) \rangle$ for the atom is given by the oscillatory decaying Bessel function $C(t) = \frac{k_B T}{m} J_0(2\omega_0 t)$, and therefore the atomic diffusion coefficient D_a is

$$D_a = \int_0^\infty dt C(t) = \frac{k_B T}{2m\omega_0}, \quad (3)$$

where recall $\omega_0 = \sqrt{k/m}$, k is the force constant, m is the mass of an atom [10]. The ratio of the diffusion coefficients for carrier hopping along a static chain (2) to that for atomic diffusion (3) can be written as

$$\frac{D_h}{D_a} = \frac{\nu}{\omega_0} \frac{ka^2}{\epsilon_0} e^{-a/L} \left\{ \frac{\epsilon_0}{k_B T} e^{-(\epsilon_0/k_B T)^2} \right\}. \quad (4)$$

The attempt frequency ν depends on many factors, but usually is of order of the characteristic phonon frequency, so the first factor ν/ω_0 is of order one. The second factor is the ratio of interaction energy of near-neighbor atoms in the chain ka^2 to the width of energy distribution of localized states ϵ_0 . Taking for estimation $k \sim 10 \text{ N/m} \sim 1 \text{ eV/\AA}^2$, $\epsilon_0 \sim 0.1 \text{ eV}$, and $a \sim 10 \text{ \AA}$, one gets for the second factor $ka^2/\epsilon_0 \sim 10^3$. This large value is typically compensated by the tunneling factor $\exp(-a/L)$, which is of order 10^{-3} for $a/L = 6$. Then the order of the ratio D_h/D_a is governed by the expression in brackets which is small for $\epsilon_0/k_B T > 1$. In what follows we shall focus on the limit $D_h/D_a \ll 1$, neglecting completely conventional hopping along the chains, and assuming that the only way for the carriers to move along the chains is be transported by diffusing localization sites.

For parallel oriented chains one can expect that transition rates for interchain hopping do not strongly fluctuate around a typical value W_{\perp} . Then the diffusion coefficient for the carrier motion in the direction perpendicular to the chains is $D_{\perp} = \frac{1}{2}W_{\perp}b^2$ where b is the distance between near-neighbor chains. For the direction along the chains the diffusion coefficient of the carriers can be estimated as

$$D_{\parallel} = \frac{1}{2}W_{\perp}\langle\Delta q^2(W_{\perp}^{-1})\rangle, \quad (5)$$

where $\langle\Delta q^2(t)\rangle$ is the atomic MSD. Indeed, a carrier, riding on a diffusing localized center, travels a distance $\Delta q(W_{\perp}^{-1})$ before jumping to another chain. For time t the number $W_{\perp}t$ of such rides occurs, and the MSD of the carrier is $\langle R^2(t)\rangle = W_{\perp}t\langle\Delta q^2(W_{\perp}^{-1})\rangle = 2D_{\parallel}t$. With $\langle\Delta q^2(t)\rangle = 2D_at$, Eq.(5) gives the diffusion coefficient for carriers D_{\parallel} equals to that for atoms

$$D_{\parallel} = D_a = \frac{k_BT}{2m\omega_0}. \quad (6)$$

It does not depend on the interchain jump frequency W_{\perp} , and increases linearly with temperature. The corresponding mobility $\mu_{\parallel} = eD_{\parallel}/k_BT$ is temperature independent, $\mu = e/2m\omega_0$. For $\omega_0 = 10^{13} \text{ s}^{-1}$ and $k = 10 \text{ N/m}$ one gets $\mu \sim 10^{-3} \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$. This value is 2-3 orders of magnitude less than in molecular crystals like anthracene, but consistent with data reported for columnar liquid crystals [3] and certain conjugated polymers [4].

The above estimation implies diffusive motion of atoms in a chain, $\langle\Delta q^2(t)\rangle = 2D_at$, which is valid for infinite chains only asymptotically, for $t \gg \omega_0^{-1}$. One may wish to improve the formula (6) using the *exact* expression for the atomic MSD which can be obtained, integrating the velocity correlation function $\langle\Delta q^2(t)\rangle = \int_0^t d\tau (t - \tau)C(\tau)$, which gives

$$\langle\Delta q^2(t)\rangle = 2D_at - \frac{D_a}{\omega_0} \varphi(2\omega_0 t) \quad (7)$$

Here the first term describes the diffusive displacement, while the second term is the more slowly growing correction with $\varphi(x) = \int_0^x d\tau \tau J_0(\tau)$. From (5) and (7) one gets $D_{\parallel} = D_a + D_ax \varphi(\frac{2}{x})$ where $x = W_{\perp}/\omega_0 \ll 1$.

Let us now discuss some elementary predictions of the model concerning mobility in an ac field of frequency ω . Since hitchhiking transport is diffusive on the long-time scale $t \gg W_{\perp}^{-1}$, one can expect that the dynamical mobility $\mu(\omega)$ in the low-frequency limit $\omega \ll W_{\perp}$ has the Drude form. We shall concentrate here on the high-frequency domain $W_{\perp} \ll \omega < \omega_0$ when interchain hopping is negligible and the response of the system is determined entirely by dynamics of the charged localized sites (atoms with attached charge carriers) driven by an external *ac* field.

The response of the chain to a local *ac* driving force $F_{ex} = e \text{Re}\{E_0 e^{i\omega t}\}$ applied to a single charged atom is convenient to analyze writing the equation of motion of the atom in the form of the non-Markovian Langevin equation [10],

$$\dot{v}(t) = -2\omega_0^2 \int_0^t dt' M(t-t')v(t') + f(t) + f_{ex}(t). \quad (8)$$

Here $f_{ex} = F_{ex}/m$, and $f(t)$ stays for the superposition of terms depending on the initial coordinate of the tagged atom, and also on the initial coordinates and velocities of all other atoms in the chain. This superposition of oscillating terms with uncorrelated phases behaves like a random function with zero average and a finite correlation time. The memory kernel

$M(t)$, which is essentially the correlation function of $f(t)$, is given explicitly by $M(t) = J_1(2\omega_0 t)/\omega_0 t$. Using Eq. (8) with $f_{ex} = 0$ one can easily find the velocity correlation function $C(t) = \langle v(0)v(t) \rangle = \frac{k_B T}{m} J_0(2\omega_0 t)$, the result which we have already used above.

Taking average of (8) and making a substitution $\langle v(t) \rangle = \text{Re}\{\mu(\omega)E_0 e^{i\omega t}\}$ one obtains for the stationary dynamical mobility $\mu(\omega)$ the expression

$$\mu(\omega) = \frac{e}{m} \frac{1}{i\omega + 2\omega_0^2 \tilde{M}(\omega)}. \quad (9)$$

Here $\tilde{M}(\omega)$ is the Laplace-Fourier transform of the damping kernel, $\tilde{M}(\omega) = \int_0^\infty dt e^{-i\omega t} M(t)$. On the other hand, one can get from Eq. (8) the transform of the velocity correlation function $\tilde{C}(\omega) = \frac{k_B T}{m} \{i\omega + 2\omega_0^2 \tilde{M}(\omega)\}^{-1}$. Comparing this with (9) one obtains the Einstein relation for dynamical mobility

$$\mu(\omega) = \frac{e}{k_B T} \tilde{C}(\omega). \quad (10)$$

Alternatively, one can express $\mu(\omega)$ in terms of the Laplace transform of the MSD $\sigma(s) = \int_0^\infty dt e^{-st} \langle \Delta q^2(t) \rangle$,

$$\mu(\omega) = \frac{e}{k_B T} (i\omega)^2 \sigma(i\omega), \quad (11)$$

which can be obtained from (10) taking into account the relation $\frac{d^2}{dt^2} \langle \Delta q^2(t) \rangle = 2 \langle v(t)v(0) \rangle$.

From (10) one finds that for $\omega < 2\omega_0$ dynamical mobility $\mu(\omega)$ is purely real,

$$\mu(\omega) = \frac{e}{m} \frac{1}{\sqrt{4\omega_0^2 - \omega^2}}. \quad (12)$$

For $\omega > 2\omega_0$ the mobility is purely imaginary and the system does not absorb energy from the field.

Dissipative chains. – Although the interchain interaction is weak in quasi 1D systems, it may determine long-time dynamics and low-frequency response of the system. Also, in many soft matter systems the chains are surrounded by solvent molecules which essentially affect dynamical properties of the system. In what follows we shall assume that both interchain and chain-solvent interactions can be modeled with the Langevin approach, i.e. by introducing in the equation of motion for a tagged i th atom the regular damping term $-\gamma \dot{q}_i$ and the random force $\xi_i(t)$,

$$m \ddot{q}_i(t) = F_i(t) - \gamma \dot{q}_i(t) + \xi_i(t), \quad (13)$$

where F_i is the force from neighboring atoms. The random force $\xi_i(t)$ is assumed to be zero centered, white noise, not correlated for different atoms,

$$\langle \xi_i(t) \rangle = 0, \quad \langle \xi_i(t) \xi_k(0) \rangle = 2k_B T \gamma \delta_{ik} \delta(t). \quad (14)$$

The motion of a tagged atom in a chain surrounded by an external bath is an example of the transport mechanism known as single file diffusion, when diffusing particles are constrained to move in one direction and are not allowed to pass each other. Single file diffusion is anomalous in the sense that the MSD of the particles asymptotically grows with time sublinearly

$$\langle \Delta q^2(t) \rangle = 2F\sqrt{t}. \quad (15)$$

For the overdamped harmonic chain the factor F is [18]

$$F = \frac{k_B T}{\omega_0 \sqrt{\pi \gamma m}}. \quad (16)$$

Hitchhiking hopping takes a place when the MSD of localized sites, Eq.(15), exceeds that for carrier diffusion due to hopping along the static chains $2D_h t$, on a time scale $t \sim W_\perp^{-1}$. This requirement leads to the condition

$$\frac{D_h}{F} W_\perp^{-1/2} \ll 1. \quad (17)$$

Suppose this inequality is satisfied, and a carrier riding on an atom for a time W_\perp^{-1} travels a distance much longer than the chain spacing a , passing many localization sites on neighbor chains. Then one can expect that the thermal factor for dominating interchain jumps is of order of one, and the typical transition rate for interchain hopping can be estimated as $W_\perp = \nu e^{-b/L}$ where b is the distance between neighboring chains. Then the condition (17) can be written in the form

$$\frac{ka^2}{\epsilon_0} \left(\frac{\gamma\nu}{m\omega_0^2} \right)^{1/2} e^{(b-2a)/2L} \left\{ \frac{\epsilon_0}{k_B T} e^{-(\epsilon_0/k_B T)^2} \right\} \ll 1. \quad (18)$$

Since the first three factors here may be large, this condition is a stronger constraint than that for the independent chains, Eq.(4). Yet it may be satisfied for sufficiently low temperature. Then the diffusion coefficient for hitchhiking transport, according to (5) and (15), is given by

$$D_\parallel = \frac{k_B T}{\omega_0} \sqrt{\frac{W_\perp}{\pi \gamma m}}. \quad (19)$$

In contrast to the approximation of noninteracting chains, D_\parallel depends on the interchain jumping rate W_\perp which may result in a weak temperature dependence of the mobility. According to Eq. (11), the dynamical mobility $\mu(\omega)$ is frequently independent for $\omega < W_\perp$, while for higher frequency it increases as $\omega^{1/2}$ as a result of subdiffusive motion (15) at $t < W_\perp^{-1}$.

These results may be improved taking into account that the single file diffusion law (15) holds only for sufficiently long time $t \gg t_c = \alpha^{-1}$, $\alpha = 2m\omega_0^2/\gamma$, while the normal diffusion with $D_a = k_B T/\gamma$ takes a place for $t < t_c$. From Eq. (13) one can obtain the *exact* expression for the MSD of a tagged atom, which is valid for the whole time scale. For the overdamped chain, $\gamma/m \gg \omega_0$, it has the form [18]

$$\langle \Delta q^2(t) \rangle = \frac{2k_B T}{\gamma} t e^{-\alpha t} \left\{ I_0(\alpha t) + I_1(\alpha t) \right\}, \quad (20)$$

where $I_n(x)$ are the modified Bessel functions. Substitution of this expression into Eq.(5) gives the general expression for D_\parallel which reduces to the form (19) for $W_\perp t_c \ll 1$, while in the opposite limit $W_\perp t_c \gg 1$ it gives $D_\parallel = D_a = k_B T/\gamma$. The dynamical mobility $\mu(\omega)$ can be estimated taking the Laplace transform of the MSD (20) and then using Eq.(11). However, separation of real and imaginary parts is easier expressing $\mu(\omega)$ in terms of the velocity correlation function $C(t)$. Using the normal mode analysis similar to that in Ref. [18], we obtained for overdamped motion

$$C(t) = \frac{k_B T}{m} e^{-\frac{\gamma}{m} t} + \frac{k_B T}{\gamma} \frac{d}{dt} \left\{ e^{-\alpha t} I_0(\alpha t) \right\}. \quad (21)$$

Then using Eq. (10) it is straightforward to get an explicit but rather lengthy expression for $\mu(\omega)$. For $\omega \ll \alpha$ it reduces to a simple function with both real and imaginary parts increasing as $\sqrt{\omega}$,

$$\mu(\omega) = \frac{e}{2\omega_0} \sqrt{\frac{\omega}{2m\gamma}} (1 - i), \quad (22)$$

while in the high frequency domain $\omega \gg \alpha$ the mobility becomes frequency independent.

In conclusion, the model of hitchhiking transport gives a simple explanation of TIM and, for dissipative chains, leads to a power frequency dependence. Such behavior may be expected for sufficiently low temperature, while for high temperature the transport is dominated by conventional hopping, and therefore, a crossover to a strong temperature dependence must occur. These predictions are consistent with experimental results discussed in the beginning of the Letter. One may speculate that the model may also be relevant to systems where the nature of the large-scale motion of localized sites is different than that for the simple model presented here. For example, conformational motion in complex biomolecules may result in the subdiffusive MSD of molecular units $\langle q^2(t) \rangle = Ft^\beta$, with $0 < \beta < 1$ and $F \sim T$ [19]. For this case Eq.(11) predicts temperature-independent hitchhiking mobility with frequency dependence $\omega^{1-\beta}$. Note that our discussion implied that the motion of atoms in a chain is unbounded, which is correct strictly speaking only for an infinitely long chain. Application of the model to finite systems may require some modification when the atomic MSD $\langle q_i^2(t) \rangle$ on a time scale of interchain jumps $t \sim W_\perp^{-1}$ becomes comparable to the upper bound given by Eq.(1). This issue, as well as the effects of zero-point fluctuations, will be addressed in a future publication. Also it would be interesting to generalize this study in the spirit of Ajdari's model of transport by active filaments [20] where carriers may spent a finite time in a solvent before being re-captured by chains.
