## Scaling behavior of a one-dim ensional correlated

disordered electronic

System

Ibrahim Avgin Department of Electrical and Electronics Engineering, Ege University, Bornova 35100, Izmir, Turkey (Dated: April 14, 2024)

## Abstract

A one-dimensional diagonal tight binding electronic system with correlated disorder is investigated. The correlation of the random potential is exponentially decaying with distance and its correlation length diverges as the concentration of "wrong sign" approaches to 1 or 0. The correlated random number sequence can be generated easily with a binary sequence similar to that of a one-dimensional spin glass system. The localization length (LL) and the integrated density of states ( $\mathbb{D} \cap S$ ) for long chains are computed. A comparison with numerical results is made with the recently developed scaling technique results. The C oherent Potential Approximation (CPA) is also adopted to obtain scaling functions for both the LL and the  $\mathbb{D} \cap S$ . We commed that the scaling functions show a crossover near the band edge and establish their relation to the concentration. For concentrations near to 0 or 1 (longer correlation length case), the scaling behavior is followed only for a very limited range of the potential strengths.

Theoretical interest in disordered chains remains strong. Recent investigations of the correlated disordered in random or chaotic arrays revealed surprising results such as a possible breakdown of the Anderson criterion for the localization [1, 2, 3, 4, 5]. Various elds have m ade use of the results obtained from the study of the one-dimensional models. Random m icrow ave transmission in a single-mode wave guide experiment [6], transport studies with G aA s-A IG aA s random dimer super lattice systems [7], and the photonic band-gap structures [8] are a few examples. Recently a new renormalization technique [9, 10] has been introduced to study the scaling behavior of the well known tight binding chain with long range correlated disorder. The authors found that the Localization Length (LL) shows scaling behavior and a cross over near the band edge. The behavior of disordered magnetic or electronic chains [11] (using proper transform ations [12, 13]) can be described mathem atically by a tri-diagonal tight binding model given by

$$(E _{n}V) _{n} = _{n+1} + _{n 1}; \qquad (1)$$

where E is energy, V is the strength of the random potential with its correlated random sign  $n \cdot n$  is the site index.

In this paper, we study the scaling properties of a particular form of correlated disorder that is associated with spin glass chains [12, 13, 14, 15]. The random sign has the relation  $n = n_1 x_n$  with the following distribution P  $(x_n) = (1 \ c) (x_n \ 1) + c (x_n + 1)$  where the  $x_n$  are uncorrelated between di erent sites and c is the concentration of "wrong signs". Clearly n is exponentially correlated, i.e.,  $h_n = (1 \ 2c)^{jn} = n^j$  where one can de ne a correlation length [16] 1(c) = 1=ln j1 2cj. For c > 0.5 the ordering is of "antiferrom agnetic type" and c = 0.5 is uncorrelated case since the correlation length is zero. A sseen in Fig. 1, for c approaching 0 or 1 the correlation length diverges.

P revious studies of the disordered chain problem showed that the electronic wave function decays exponentially with a distance [17] characterized by the real part of the Lyapunov exponent [18] whose in aginary part is also related to the Integrated D ensity of States (ID O S) [18]. In our work num erical calculations are carried out for chains of  $10^8$  sites using the negative eigenvalue counting technique introduced by D ean [19] providing direct computation of the Lyapunov exponent.

Recently the scaling properties arising from long range correlated disorder [9, 10] were in-

vestigated using the renorm alization approach. The authors have argued that their analyses work close to the band edge where the characteristic wavelength diverges since neighboring lattice sites move as blocks. Here we adopt their results for the correlated case discussed above.

The complex Laypunov exponent [18] is defined as  $(E;V;c) = \lim_{N \to 1} \ln \frac{1}{N} \ln \frac{N}{0}$ . The space decimation procedure [10] leads to rede ming the random potential by its mean value over the block, i.e.,  $V_N = \int_{n=1}^{P} V_n$ . The square of this scaled potential has mite value proportional to N with increasing N for all concentrations as displayed in Fig.1. For c > 0.5, the sum m ation has alternating values particularly persistent for c = 1 but eventually reaches to a limiting value discussed below for larger N (see Fig. 1). For uncorrelated case exact scaling results exist for the LL and the ID OS defined value displays a scaling law of the form [18]  $< V^2 > 1=3$  h ( $\frac{2}{\sqrt{V^2} > 2=3}$ ) where h explicitly known scaling function. For the correlated case, it was assumed that the Lyapunov exponent [10] has similar power-law relation to the second moment of the redefined and potential (note that the first moment is zero)  $< V_N^2 >$  which can be written for our case as:

$$\langle V_{\rm N}^2 \rangle = \frac{V_{\rm N}^2}{{\rm N}} = \frac{1}{{\rm C}} {\rm V}^2$$
: (2)

Detailed account of this factor is given in Ref.[12, 20] This factor (in fact its 1=3 power)  $\frac{1 c}{c}$  is shown in Fig. 1 and it plays a role in the scaling behavior discussed below. Unlike the correlation length it diverges as c! 0 while it remains nite as c! 1.

At the band edge E = 2, according to the analysis of Ref.[10] the space decimation for blocks of b sites results in the following scaling: the strength of the potential must hold (to preserve the form of the Eq. (1) V !  $V_b = bV$  (see Eq.(7-11) of Ref.[10]), hence the second moment transform  $s < V_{N_b}^2 > = b\frac{1 c}{c} (bV)^2 = b^3 < V_N^2 >$ . This corresponds to their [10] case of = 1. Thus The Lyapunov exponent at the band edge can be written in a form [10, 18] (E = 2;V;c) =  $(< V_N^2 >)^{1=3} = (V^2 \frac{1 c}{c})^{1=3}$ . The power of the Lyapunov exponent is the same as the uncorrelated case [18] but the coe cient is di erent. The factor involving concentration was recovered before using phenom elogical arguments in the context of the spin glass chain [12, 20]. The exact results for uncorrelated case c = 0.5 are well known [18] given by ID OS =  $\frac{1}{c} = 0.159V^{2=3}$  and  $\frac{1}{LL} = < 0.289V^{2=3}$ . In an earlier work we

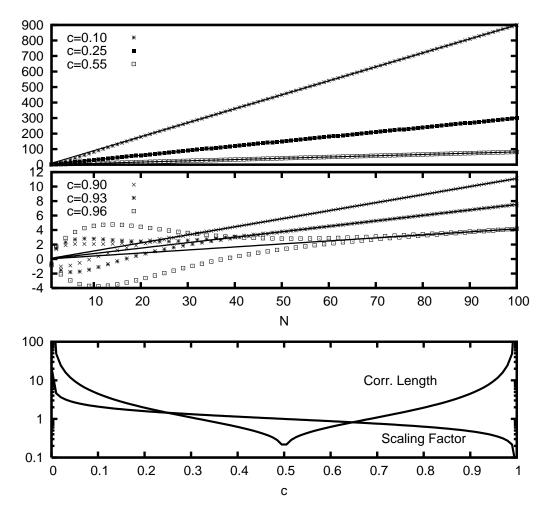

FIG.1: The low erpanel is a plot of the scaling factor  $(\frac{1}{c})^{1=3}$  and the correlation length l(c) versus c. l(c) is sym m etric about c = 0.5 and zero at this concentration. The square of the potential  $V_N^2$  versus the number of cites are presented at the upper panels with respective concentrations. The lines are  $V_N^2 = \frac{1}{c}N$  obtained for a large N and the points are calculated by a nite sum mation of  $V_N^2$ .

showed that the  $\mathbb{D} \cap S$  and the LL [12, 14, 20] results for various concentrations scaled with a similar factor where data collapsed well to the exact calculation at c = 0.5.

For uncorrelated case it is known that there is a cross over limit when w 2 E is positive and very sm all [9, 18]. In this limit, the Lyapunov exponent can be written in the form

(w;V;c) 
$$(V^2 \frac{1-c}{c})^{1=3} F(X)$$
 (3)

where X w ( $V^{2\frac{1}{c}}$ )<sup>2=3</sup> and F (X) is the scaling function. From the previous studies it was found [9, 18] that the scaling function has di erent behaviors for X << 1 and X >> 1, hence there is a cross over between these two limits. It was argued [9] that in this system the cross over is a consequence of the competition between the characteristic length of the wave function and the LL and the two asymptotic regimes can be obtained by the dom inance of the LL or . When >> LL where w ! 0 the wave function is independent of since it would decay over a distance of and the LL does not deviate much from its value at the band edge so that F (x) ! constant. In the other limit LL >> where the wave function would have considerable oscillations before decaying, the LL has a di erent functional dependence on the strength of the random potential [9, 18], i.e., LL < V<sup>2</sup> > since w dom inates the dynam ics yielding F (X) ! X.

Insight can be gained if we adopt the C oherent P otential Approximation (CPA) results here. The CPA self energy or the coherent potential has important connections to the system 's dynamics which for uncorrelated disorder [21, 22] can be written as  $V_c$  '  $(\frac{\langle V^2 \rangle}{2i})^{2=3}$ . For correlated random potentials we can substitute here the second m on ent of the potential given in Eq. (2) (so that the correlations between di erent sites are included) then the coherent potential takes this form  $V_c = (\frac{1 c}{c} \frac{V^2}{2i})^{2=3}$ . The dispersion relation can be obtained from the poles of the con gurationally averaged k dependent G reen function [21] that E  $\langle V_c = 2\cos k$  where k is a wave vector. For sm all k, it can be reform ulated as  $k^2$  '  $\langle V_c + w$ . A way from the band edge the LL was calculated before [9, 18, 22] and can be expressed as  $LL = \frac{8\sin^2 k}{\langle V^2 \rangle}$ . Recalling the fact that in one dimension k is proportional to the DOS, both the LL and the DOS can be rearranged yielding the scaling functions respectively  $F(x) = LL(\frac{1 c}{c}V^2)^{1=3} = 8(2^{5=3} + X)$  and  $G(x) = IDOS(\frac{1 c}{c}V^2)^{1=3} = \frac{1}{2} \frac{P}{2^{5=3} + X}$  where G (X) has di erent asymptotic behavior when X >> 1, G (X) !  $\frac{P}{X}$ .

We present our numerical and the CPA results below. We have calculated the scaling functions F (X) and G (X) for chains of  $10^8$  sites using the negative eigenvalue counting technique. As shown in Fig. 1 (sem i-logarithm ic plot) the correlation length goes to zero as c ! 0.5 and increases with increasing jc 0.5 jwith a rapid increase developing near c ! 1;0. The results presented in Fig. 2 are for shorter correlation lengths where c = 0.1;0.25;0.5;0.75;0.9 and for w =  $10^4$  and  $10^3$ . The data clearly indicate that there is a scaling function for both the LL and DOS. The CPA under estimates the scaling function for the LL but reproduces the DOS results rather well as shown in gures presented in this

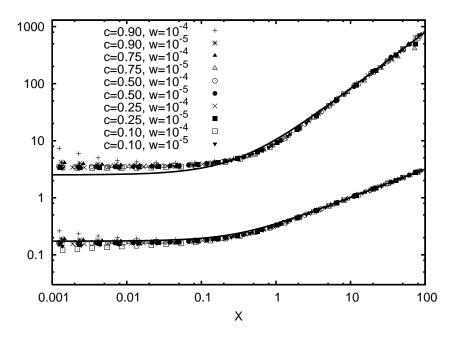

FIG. 2: plot of F (X) (top) and G (X) (bottom) as function of the scaling variable X w ( $V^{2\frac{1}{c}}$ )<sup>2=3</sup> strength V. The lines are the CPA results. section. We have found that for  $w > 10^4$  the scaling functions some what deviate from the expected scaling behavior near the lower values of X. However for  $w < 10^4$  they follow the predicted results.

For concentrations near 0;1 a region of rapidly increasing correlation length, we produced two sets of data displayed in Fig. 3 and Fig. 4. In Fig. 3 the scaling functions are displayed for concentrations c = 0:1;0:05;0:9; and 0:95; where the rapid increase in the correlation length starts. The scaling behavior is observed for only w  $10^{-6}$ . Note that we obtained sim ilar, even better scaling behavior for the concentrations presented in Fig. 2 with w  $10^{-6}$ values.

The scaling behavior is also clearly revealed in Fig. 4 where the deviations near the lower limit are generally largest for  $w = 10^{6}$ . The concentrations here are very close to 0;1, as presented in gure caption, so one has to go to very small values of w ( xed V) to see the scaling behavior. The shrinking of the scaling region in w as c ! 0;1 is consistent with the behavior for c = 0;1, where the correlation length is in nite. The collapse of the data for di erent values of c is a feature of the model that rejects the fact that both the second moment (Eq. (2) and the correlation length are functions of c. The DOS results

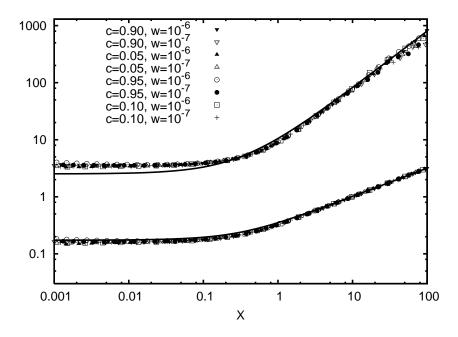

FIG. 3: plot of F (X) (top) and G (X) (bottom) as function of the scaling variable X w ( $V^{2\frac{1}{c}}$ )<sup>2=3</sup> strength V. The lines are the CPA results. The data displayed for the concentrations c = 0:1;0:05;0:9;0:95 and the two energies w = 2 E = 10<sup>6</sup> and 10<sup>7</sup>.

also deviate for this range of concentrations. Thus as the correlation length is increased, the scaling behavior can be observed only for smaller and smaller values of w; however, we found that w cannot be reduced as much as desired. Hence after certain small w, deviations starts this time particularly at higher X sides. Thus there is a trade-o in building the scaling variable X since it depends on the three parameters w, c and V and only delicate combination of these parameters produces scaling and the crossover behavior. Stronger deviations presented in Fig. 3-4 at very small X for the concentrations near 0;1 show this sensitive dependence. Because very small concentrations, the scaling factor becomes very small or very large, therefore the Lyapunov exponent must be computed in a region of a very small or a very large potential strengths at very small w wherein the computational errors inevitable or the scaling behavior of the Lyapunov exponent holds only very limited potential strengths V.

We have studied binary correlated disordered chains both analytically and numerically. The LL and the  $\mathbb{D} \cap S$  are computed for various concentrations. We found that they both showed a scaling behavior and a crossover. The behavior of the scaling functions predicted by the renorm alization group techniques [9, 10] is observed. The data calculated numerically

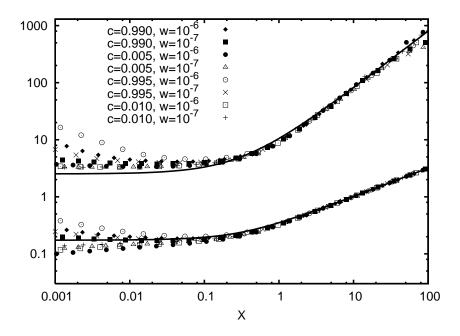

FIG. 4: plot of F (X) (top) and G (X) (bottom) as function of the scaling variable X w ( $V^{2\frac{1}{c}}$ )<sup>2=3</sup> strength V. The lines are the CPA results. The data displayed for the concentrations c = 0:01;0:005;0:99;0:995 and the two energies w = 2 E = 10<sup>6</sup> and 10<sup>7</sup>.

for various concentrations with increasing correlation length largely collapsed to scaling functions belonging to the LL and DOS separately. The scaling factor as a function of concentration plays a key role in the scaling behavior of the LL and DOS data. The scaling behavior obtained here holds for a more limited range of w values than that obtained by Russ et al. [9]. For instance we did not see any scaling behavior when  $w > 10^4$ , whereas they presented the scaling behavior for  $w = 10^{1}$  10<sup>5</sup>. For the scaling near the limiting concentrations, some scattered data are obtained for lower values of the scaling variable X. We have used scaling arguments and established the scaling functions for both the LL and the DOS using the CPA results. The CPA results reproduced data for the ILL rather qualitatively but surprisingly for the DOS it reproduced the data rather well. This study revealed that if the second moment of the correlated random potential is calculated, then the CPA results can be implemented as the way presented here even though the CPA was developed m ainly for noncorrelated random potentials.

We have bene ted from discussions with Prof. D.L.Huber. This work is partially
