(December 31, 2021)

Recent measurements of the 2D Hall resistance show that the Hall coefficient is independent of the applied in-plane magnetic field, i.e., the spin-polarization of the system. We calculate the weak-field Hall coefficient and the magnetoresistance of a spin-polarized 2D system using the semi-classical transport approach based on the screening theory. We solve the coupled kinetic equations of the two carrier system including electron-electron interaction. We find that the in-plane magnetic field dependence of the Hall coefficient is suppressed by the weakening of screening and the electron-electron interaction. However, the in-plane magnetoresistance is mostly determined by the change of the screening of the system, and can therefore be strongly field dependent.

PACS Number : 72.25.Rb; 72.15.Gd; 73.40.Qv

The phenomena of apparent two dimensional (2D) metallic behavior and the associated 2D metal-insulator transition (MIT) continue to attract a great deal of attention [1,2]. The low temperature resistivity ( $\rho$ ), in zero applied field, shows remarkably strong "metallic"-like (i.e.  $d\rho/dT > 0$  for  $n > n_c$ ) temperature dependence for 2D carrier densities above the so-called critical carrier density ( $n_c$ ) for the 2D MIT whereas, for  $n < n_c$ , the system exhibits insulating behavior ( $d\rho/dT < 0$ ). The application of an in-plane magnetic field  $B$  has interesting effects on the 2D metallic phase, i.e., at a fixed low  $T$  the system develops a large positive magnetoresistance with  $\rho(B)$  increasing very strongly (by as much as a factor of 4) with  $B$  up to a maximum field  $B_s$ , and for  $B > B_s$ ,  $\rho(B)$  either saturates (or increases slowly with  $B$  for  $B > B_s$ ) showing a distinct kink at  $B = B_s$  [3]. The observed temperature, density, and parallel magnetic dependence of the 2D "metallic" resistivity [2,4] can be explained by the screening theory in which the strongly temperature dependent effective screened charged impurity disorder is the qualitative reason underlying the striking metallic behavior of dilute 2D carrier systems.

Remarkably, recent measurements of the 2D Hall resistance [5] in a parallel magnetic field have shown unexpected physical behavior which is in sharp contrast with the strong in-plane field dependence of the 2D magnetoresistivity. The measured Hall coefficient seems to contradict qualitatively the results based on the screening theory [6] even though the longitudinal magnetoresistance can be explained by the change of the screening as the spin-polarization of the system varies. The measured Hall coefficient is found not to vary with parallel magnetic field (or spin-polarization) for fields ranging from 0 to well above  $B_s$ , where  $B_s$  is the complete spin-polarization field. However, the screening theory shows very strong magnetic field (spin-polarization) dependence. Since the screening theory, at least in its most elementary formulation [6], cannot explain this unexpected Hall coefficient data Vitkalov et al. [5] proclaim that the electron-electron inter-subband scattering in the

spin-polarized system is the main reason for the experimental behavior. The qualitative disagreement between the experimental Hall data of ref. [5] and the screening theory [6] is therefore a problem in our fundamental understanding of 2D transport because the screening theory [7] can explain the temperature dependent Hall coefficient in p-GaAs [8] and SiMOSFET [9].

Motivated by this puzzling experimental observation [5], we investigate in this paper, based on the screening model, the spin-polarization dependence of the weak-field Hall resistance and magnetoresistance. For complete comparison with the experimental Hall coefficient we include in our calculation the electron-electron scattering between two different spin subbands. In ref. [5] Vitkalov et al. compare the Hall coefficient data with the zero temperature results of screening theory [6] in the strong screening limits  $q_{TF} = 2k_F \gg 1$  (where  $q_{TF}$  is the Thomas-Fermi screening wave vector and  $k_F$  is the Fermi wave vector). Our calculation, which includes finite temperature and fully wave vector dependent screening, is in qualitative agreement with the experimental results [5] on the spin-polarization dependence of the weak-field Hall coefficient although electron-electron scattering might play a role at finite temperature as we show. We therefore resolve the experimental problem posed in ref. [5].

To calculate the Hall coefficient and the magnetoresistance, we solve the coupled kinetic equations for two kinds of carriers. When the parallel magnetic field is applied to the system the electron densities  $n_{\uparrow}$  for spin up/down are not equal with the total density  $n = n_{\uparrow} + n_{\downarrow}$ . The spin-polarized densities themselves are obtained from the relative shifts in the spin up and down bands introduced by the Zeeman splitting associated with the external applied field  $B$ . Since there are two groups of electrons (spin up and down) we need to consider inter-spin-band electron-electron scattering, which contributes to resistivity in addition to electron scattering by charged impurities and phonons. In the presence of an applied field, the carrier momentum will relax to

FIG. 1. Normalized Hall coefficient  $R_H(B)=R_H(0)$  as a function of in plane magnetic field (spin polarization of the system) for different densities,  $n = 1, 10, 50, 100 \text{ } 10^{10} \text{ cm}^{-2}$  and at  $T = 0\text{K}$ . At  $B = B_s$  the 2D system is completely spin-polarized.

equilibrium by electron-electron, electron-impurity, and electron-phonon scattering (which is neglected in this calculation because at low temperatures of interest to us phonon scattering is unimportant). The electron-electron relaxation rate  $\tau_{ee}$  will only affect the relative momentum (i.e. the electron-electron scattering for the same spin is neglected in this calculation). The electron-electron scattering relaxes the relative velocity or relative momentum between two different populations to zero. In the steady state, the kinetic equations of motion in the presence of an electric field  $E$  and magnetic field  $B$  for spin up/down electrons, taking into account the collisions with spin down/up electrons, have the form ( $c = \hbar = 1$ ) [11]

$$\begin{aligned} m_1 \frac{v_1}{1} + M \frac{n_2 v_1 - v_2}{n_{ee}} &= eE + e(v_1 - B); \\ m_2 \frac{v_2}{2} + M \frac{n_1 v_2 - v_1}{n_{ee}} &= eE + e(v_2 - B); \end{aligned} \quad (1)$$

where  $m_i$  is the effective mass ( $i = 1, 2$  denotes up/down spin subbands) for each group,  $M = nm_1m_2/(m_1n_1 + m_2n_2)$ , and  $\tau_i$  is the (energy and temperature dependent) 2D carrier transport scattering time (the so-called momentum relaxation time) determined by the screened charged impurity scattering [10] and  $\tau_{ee}$  is the electron-electron relaxation time for the relative momentum of the spin polarized system.

By solving the system of equation for  $v_i$  and substituting these velocities into expression for the current density  $j = n_+ev_+ + n_2ev_-$ , we find the resistivities  $\rho_{xx}$  and  $\rho_{xy}$ ,

$$\rho_{xx} = \frac{1}{ne} \frac{\hbar^2 i \left[ 1 + \frac{n_1 n_2 + n_2 n_1}{n_{ee}} + \frac{n_1 n_2 (n_1 n_2 + n_2 n_1)}{n} B_z^2 \right]}{\left[ \hbar^2 i + \frac{n_1 n_2}{\tau_{ee}} \right]^2 + (n_1 n_2 B_z)^2}; \quad (2)$$

$$\rho_{xy} = \frac{B_z}{ne} \rho_{xx} i; \quad (3)$$

FIG. 2. Calculated Hall coefficient  $R_H(B)=R_H(0)$  as a function of in plane magnetic field (spin polarization of the system) for different temperatures,  $T = 0, 1, 2\text{K}$ , and  $n = 20 \text{ } 10^{10} \text{ cm}^{-2}$ .

where  $\hbar^2 i = \hbar^2 i + \frac{n_1 n_2}{\tau_{ee}}$  and  $B_z$  is the applied magnetic field normal to the 2D layer and  $\mu$ , the so-called Hall ratio, is given by

$$\mu_{\text{Hall}} i = 1 + \frac{\hbar^2 i - \hbar^2 i^2}{\left[ \hbar^2 i + \frac{n_1 n_2}{\tau_{ee}} \right]^2 + (n_1 n_2 B_z)^2}; \quad (4)$$

Here  $i = e_i/m_i$  and  $\tau_{ee} = e_{ee}/M$  and the average mobility is defined by  $\hbar^2 i = (n_1 n_1 + n_2 n_2)/n$  and  $\hbar^2 i^2 = (n_1^2 n_1 + n_2^2 n_2)/n$ . When inter-subband electron-electron scattering is weaker than the impurity transport scattering times ( $\tau_{ee} \gg \tau_i$ ) we have  $\rho_{xx} = 1/ne\hbar^2 i$  and  $\mu_{\text{Hall}} i = \hbar^2 i/\hbar^2 i^2$ . In the other limit,  $\tau_{ee} \ll \tau_i$ , we have  $\rho_{xx} = (n_1/n_1 + n_2/n_2)/ne$  and  $\mu_{\text{Hall}} i \ll 1$ . These equations immediately imply that the Hall coefficient will have very weak temperature dependence (i.e.  $\rho_{\text{Hall}} \approx 1$ ) when the inter-spin subband electron-electron scattering dominates over the impurity scattering.

In Figs. 1 and 2 we show our calculated Hall coefficient without inter-subband electron-electron scattering. In this case the total conductivity is the sum of the conductivities of each group,  $\sigma = \sigma_1 + \sigma_2$ , and the Hall coefficient is given by  $\mu_{\text{Hall}} i = \hbar^2 i/\hbar^2 i^2$ . Throughout this paper we use the parameters corresponding to Si-MOSFET electron systems following ref. [5]. In Fig. 1 we show our calculated Hall coefficient,  $R_H(B)=R_H(0)$ , ( $R_H = \mu_{\text{Hall}} i/ne$ ) for several carrier densities,  $n = 1, 10, 50, 100 \text{ } 10^{10} \text{ cm}^{-2}$  (which correspond to the screening strength  $q_{TF} = 2k_F = 35, 11, 5, 3.5$  respectively) as a function of in-plane magnetic fields at  $T = 0$ . As in-plane magnetic field increases the spins are polarized, and at  $B = B_s$  the system is completely spin-polarized. In the low density limit (strong screening,  $q_{TF} = 2k_F \gg 1$ ) the normalized Hall coefficient is strongly dependent on the polarization of the system. But for high densities (weak screening) the coefficient is almost independent of the spin polarization. Thus the polarization dependent

FIG. 3. Calculated inter spin-subband electron-electron scattering times for different temperatures  $T = 0.5, 1.0, 2.0\text{K}$  as a function of the parallel magnetic field. We use the 2D density  $n = 20 \times 10^{10}\text{cm}^{-2}$ .

Hall coefficient is suppressed as screening effects decrease. We find that the normalized Hall coefficient for a density  $n = 25 \times 10^{10}\text{cm}^{-2}$  (corresponding to ref. [5]) increases only about 6% at most as the system gets fully spin-polarized by the applied field.

Since the screening function is suppressed by thermal effects we expect the Hall coefficient to be suppressed at finite temperatures. In Fig. 2 we show our calculated Hall coefficient,  $R_H(B)$ , for several temperatures,  $T = 0, 1, 2\text{K}$  and a fixed density  $n = 20 \times 10^{10}\text{cm}^{-2}$ . As the temperature increases the normalized Hall coefficient shows suppressed field dependence mostly due to the weakening of the screening. Comparison between our results and the experimental results [5] shows good qualitative agreement. Thus, the observed field independence of the Hall coefficient can be qualitatively explained by the screening theory. However, in ref. [5] Vikařov et al. conclude, by comparing their measured Hall coefficient (which does not vary with parallel magnetic field) with the theoretical expectations based on the screening theory [6] calculated in the strong screening limit ( $q_T = k_F = 1$ ) and at zero temperature, that the screening theory disagrees qualitatively with the experimental Hall effect results, and therefore the strong electron-electron scattering is a possible explanation for their data. In order to investigate the effects of electron-electron scattering on the Hall coefficient we consider fully Eq. (4) which includes electron-electron scattering as well as the screened charged impurities. We explicitly calculate the electron-electron scattering time  $\tau_{ee}$  defined as the relaxation time of the relative momentum between spin up and down carriers [12]. For an unequal spin population we have  $\tau_{ee}$

$$\frac{1}{\tau_{ee}} = \frac{8(k_B T)^2}{3(\epsilon)^2} \frac{\text{nm}^3}{n_1 n_2} \int_0^Z p_0 d \sin \frac{2e^2}{q''(q)} [f(p)]^2 \quad (5)$$

where  $f(p) = (1 + p^2 + 2p \cos \theta)^{1/2}$  with  $p = (n_1 - n_2)^{1/2}$ ,

FIG. 4. Calculated Hall coefficient  $R_H(B) = R_H(0)$  as a function of in-plane magnetic field (spin polarization of the system) for different temperatures,  $T = 0, 1, 2\text{K}$ , and  $n = 20 \times 10^{10}\text{cm}^{-2}$ . Thick (thin) lines indicate the results with (without) electron-electron scattering.

$q = 4 \sqrt{p n_1 n_2} \sin(\theta) = f(p)$ , and  $\epsilon(q)$  is the total dielectric function of the system. Thus we have that  $\tau_{ee}^{-1} \propto T^2$ . In the very low temperature limit we expect the contribution of the electron-electron scattering to the Hall coefficient to be negligible because of this  $T^2$  dependence of  $\tau_{ee}^{-1}$ . At low temperature, therefore ( $T \ll T_F$ ) our results (Figs. 1 and 2) neglecting  $\tau_{ee}$  effects apply.

In Fig. 3 we show our calculated inter spin-subband electron-electron scattering times,  $\tau_{ee}$ , as a function of the parallel field (or spin-polarization) and temperature. (Note in ref. [5] a constant parameter  $\tau_{ee}$  is used to fit the Hall coefficient data, which is incorrect.) In general, we find the elastic scattering time due to ionized impurities at the interface to be  $\tau_i \approx 7\text{ps}$  with an impurity density  $n_i = 3 \times 10^{10}\text{cm}^{-2}$ , which corresponds to the experimental Si-MOSFET sample of the mobility  $\mu = 2 \times 10^4 \text{V/cm}^2\text{s}$ . Thus the calculated  $\tau_{ee}$  is much larger than the elastic scattering time  $\tau_i$  in the low temperature limit where the 2D experiments are typically carried out.

With the results in Fig. 3 we calculate the Hall coefficient of the spin-polarized system including electron-electron scattering. Fig. 4 shows the calculated Hall coefficient  $R_H(B) = R_H(0)$  as a function of in-plane magnetic field for different temperatures,  $T = 0, 1, 2\text{K}$ , and  $n = 20 \times 10^{10}\text{cm}^{-2}$ . Our calculation shows that the electron-electron scattering leads to the further suppression in the field dependence of the Hall coefficient, leading to even better agreement between experiment [5] and our theory.

Fig. 5 shows the calculated magnetoresistance as a function of in-plane magnetic field for different temperatures and a carrier density  $n = 2 \times 10^{11}\text{cm}^{-2}$ . This strong positive magnetoresistance can be explained by the sys-

FIG. 5. Calculated magnetoresistance as a function of in-plane magnetic field for different temperatures,  $T = 0, 1, 2\text{K}$  (from bottom to top). The results are shown for the carrier density  $n = 2 \times 10^{11} \text{cm}^{-2}$ . The solid (dashed) lines indicate calculated results without (with) electron-electron inter-spin subband scattering.

tematic suppression of screening as the spin-polarization of the system changes [4,6]. The saturation of the magnetoresistance above  $B_s$  is attributed to the complete spin-polarization of the system. Considering electron-electron scattering in the calculation produces very small quantitative modification in the magnetoresistance even though the electron-electron scattering times are comparable to the elastic impurity scattering times (at  $T = 2\text{K}$ ). In Fig. 5 the solid (dashed) lines indicate calculated results without (with) electron-electron interaction. Even though the electron-electron scattering rate is stronger than the elastic scattering rate, the calculated magnetoresistance shows the same behavior. Thus, the experimentally measured strong positive magnetoresistance with increasing in-plane magnetic field is induced mostly by the change of the screening properties, not by the inter-spin subband electron-electron scattering.

In Fig. 6 we show that calculated longitudinal magnetoresistance  $\rho_{xx}$  as a function of perpendicular magnetic field ( $B_z$ ) for different temperatures,  $T = 0, 1, 2\text{K}$ . The in-plane parallel magnetic field solely gives rise to the spin polarization of the system. The results are shown for a carrier density  $n = 2 \times 10^{11} \text{cm}^{-2}$  and a fixed in-plane magnetic field  $B_x = 0.5B_s$ . For an unpolarized system (i.e., a single subband with an isotropic scattering rate) classical transport theory predicts no magnetoresistance (horizontal solid line in Fig. 6) since the Hall field exactly compensates the Lorentz force and the carriers drift in the direction of the applied field. In fact, single subband systems typically exhibit a negative magnetoresistance due to quantum corrections arising from weak localization or electron-electron interactions [13]. For a system with two different Fermi wave vectors (two occupied subbands) the classical transport theory predicts a positive magnetoresistance varying quadratically with magnetic

FIG. 6. Calculated magnetoresistance as a function of perpendicular magnetic field ( $B_z$ ) to the 2D plane for different temperatures,  $T = 0, 1, 2\text{K}$  (from bottom). The results are shown for the carrier density  $n = 2 \times 10^{11} \text{cm}^{-2}$  and a fixed in-plane magnetic field  $B_x = 0.5B_s$ . The thick (dashed) lines represent results with (without) electron-electron interaction.

field  $B_z$  at low fields and saturating at higher fields. In Fig. 6 we have the positive magnetoresistance as the magnetic field increases for a spin-polarized system. The positive magnetoresistance is again reduced by thermal effects (weakening of screening), and also by the electron-electron scattering (assuming that there are no quantum corrections).

In conclusion, we calculate the weak-field Hall coefficient and the magnetoresistance of a spin polarized system based on the screening theory. We find that the spin-polarization dependence of the Hall coefficient is strongly suppressed by the weakening of screening. The electron-electron inter-spin subband scattering gives rise to an additional suppression of the Hall coefficient, but in the low temperature experimental regime the inter-spin subband electron-electron scattering is not quantitatively important. Our theory provides a very good explanation for recent experiments [5] on the magnetic field dependence of the 2D Hall coefficient.
