(Dated: April 14, 2024)

We have studied the nonequilibrium dynamics of spin glasses subjected to bond perturbation, which was based on the direct change in the spin-spin interaction J , using photo illumination in addition to temperature change T . Differences in time-dependent magnetization are observed between that under $T + J$ and T perturbations with the same T . This difference shows the contribution of J to spin-glass dynamics through the decrease in the overlap length. That is, the overlap length L_{T+J} under $T + J$ perturbation is less than L_T under T perturbation. Furthermore, we observe the crossover between weakly and strongly perturbed regimes under bond cycling accompanied by temperature cycling. These effects of bond perturbation strongly indicate the existence of both chaos and the overlap length.

I. INTRODUCTION

Spin glass has been studied for the past several decades, but many questions about the nonequilibrium dynamics of spin glass still remain. To clarify the nature of spin glass below the transition temperature, the aging behavior¹ in the relaxation of magnetization in spin glasses has been actively studied. Especially, the aging of spin glasses subjected to perturbations X , such as changes in temperature T and in bond interaction J , has been extensively studied because it shows characteristic behaviors peculiar to spin glasses, such as memory and rejuvenation.^{2,3} These behaviors were interpreted in terms of the phenomenological scaling theory, called the droplet model.^{4,5,6} According to this theory, the memory and rejuvenation effects are explained in terms of the concept of chaos accompanied by the overlap length L_X .^{4,6} The correlation between two equilibrium states, before and after the perturbation, disappears at the length scale L beyond the overlap length L_X . However, the chaotic nature appears even at weak perturbation X that satisfies $L < L_X$.^{7,8,9} At strong perturbation X that satisfies $L > L_X$, the aging effect before the perturbation is not easily removed, but the memory effect is observed. These contradictory aspects can be explained based on the ghost domain scenario.^{7,10,11,12} Thus, the crossover between a weakly perturbed regime ($L < L_X$) and a strongly perturbed regime ($L > L_X$)^{11,12} should be clarified so that we can gain an intrinsic understanding of the rejuvenation and memory effects based on the droplet picture.

So far, the experimental studies^{12,13,14,15,16} and simulations^{17,18,19} of spin glasses, have been conducted exclusively under the temperature cycling protocol. In such an experimental protocol based on temperature change, however, this change inevitably affects the thermal excitation of the droplet and thus leads to strong separation of the time scales.¹⁰ This makes it difficult to demonstrate the existence of temperature chaos. In

fact, several papers^{18,19,20,21} claim that the rejuvenation-memory effects observed in temperature cycling can be attributed to the differences among the length scales caused by the change in temperature. If the direct change in the bond, J , can be used in this kind of experiment without the change in time scales, it is expected that the chaotic effect and the overlap length could be more clearly analyzed.

The direct change in the spin-spin interaction J can be realized through the photo excitation of carriers using a semiconductor spin glass, e.g., $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$.^{22,23,24,25} The relaxation in thermomagnetic magnetization and that in isothermal remanent magnetization of $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ were observed under unpolarized light illumination.²⁶ Recently, we studied the aging behavior of $\text{Cd}_{1-x}\text{Mn}_x\text{Te}$ under photo illumination, and showed that the J contribution can be deduced by comparing the data under the $T + J$ and T perturbations with the same T .²⁷ To date, however, there has been no systematic study of aging behavior under bond perturbation. It is essential to obtain evidence of the existence of the chaotic effect and of the change in the overlap length expected in the droplet model^{4,5} through the analysis of bond perturbation data.

In this study we first confirm that bond perturbation using photo illumination affects the spin-glass dynamics. We estimated that $J = 0.14 - 0.40\text{K}$ at $T = 0.26\text{K}$. The second purpose is to clarify the characteristics of overlap length and to specify the crossover between weakly and strongly perturbed regimes to demonstrate the validity of the droplet picture.

II. EXPERIMENTAL DETAILS

The sample was a single crystal of $\text{Cd}_{0.63}\text{Mn}_{0.37}\text{Te}$ (band gap energy $E_g = 2.18\text{eV}$) that was prepared using the vertical Bridgman technique. The magnetization of the sample, which was a plate 1.2mm thick, was

FIG. 1: Temperature dependence of ZFC and FC magnetizations of $\text{Cd}_{0.63}\text{Mn}_{0.37}\text{Te}$ in $H = 100$ Oe. The freezing temperature of 10.7K estimated by this graph. The inset shows the field dependence of the magnetization at 7K ($= T_m$).

measured by a Quantum Design MPMS5 superconducting quantum interference device (SQUID) magnetometer. Figure 1 shows the temperature dependent magnetization under FC (field-cooled) and ZFC (zero-field-cooled) conditions in $H = 1000$ e.²⁹ The spin-freezing temperature $T_f = 10.7\text{K}$ was evaluated. Light was guided to the sample through a quartz optical fiber so as to be parallel to an external magnetic field. The light source was a green He-Ne laser with $\lambda = 543.5\text{nm}$, (2.281eV), where this photon energy was slightly larger than the band gap energy of the sample. One side of the sample was coated with carbon. If light was illuminated on the carbon-coated side, the light was absorbed in a carbon black body and, thus only the thermal contribution ΔT appeared. When the light was illuminated on the opposite side, a change in bond interaction ΔJ appeared in addition to ΔT .²⁸ We determined the sample temperature during the illumination based on the change in field-cooled magnetization as shown in FIG. 1. The photo-induced magnetization in $\text{Cd}_{0.63}\text{Mn}_{0.37}\text{Te}$ was scarcely observed (less than 0.01 of the total magnetization change by the photo illumination),²⁸ and thus we were able to neglect it. The light intensity was adjusted so as to obtain the same increment of sample temperatures under both the illumination conditions. This made it possible to consider only the ΔJ contribution by comparing the $T + \Delta J$ data with the T data. We note that the change in temperature by the illumination was given to a sample with step-like heating and cooling.²⁸ Thus we could also neglect the effect of the finite cooling/heating rate.^{12,17}

The time dependence of magnetization was measured according to the following procedure. (Fig. 2) The sample was zero-field-cooled down to T_m as rapidly as possi-

FIG. 2: Experimental protocol of bond-cycling process under photo illumination. The sample was first cooled to $T_m = 7\text{K}$ and aged during $t_w = 3000\text{s}$ (initial aging stage). The perturbation was subsequently added during t_p (perturbation stage) using photo illumination. After the perturbation was stopped, H of 100 Oe was applied and the magnetization was measured as a function of t (healing stage).

ble ($\sim 10\text{K/m in}$) from 30K which is above the transition temperature T_g . Then, the temperature T_m was held for $t_w (= 3000\text{s})$ (initial aging stage). After that, the perturbation was given to the sample during t_p using the photo illumination (perturbation stage). After the light was turned off, a magnetic field H of 100 Oe, at which the linear field-dependent magnetization was held (inset of FIG. 1)), was subsequently applied. After $t_s = 60\text{s}$, the magnetic field H of 100 Oe is stabilized, and then the magnetization M was measured as a function of time t (healing stage).

The dynamics of a spin glass below T_g is governed by excitations of the droplet.⁴ The size $L_{T_m}(t)$ of the droplet, which was thermally activated at T_m within the time scale t , is given by the following equation,⁴

$$L_{T_m}(t) = L_0 \frac{k_B T_m \ln(t/t_0)^{1/4}}{(T_m)} : \quad (1)$$

Consequently, a significant difference in time scales existed even between two close temperatures, T_m and $T_m + \Delta T$. Therefore, we define the effective duration $t_e(T_m)$ of the perturbation¹⁰ according to

$$L_{T_m + \Delta T}(t_p) = L_{T_m}(t_e); \quad (2)$$

or

$$t_p(T_m + \Delta T) = t_0 (t_e(T_m) = t_0)^{T_m/(T_m + \Delta T)}; \quad (3)$$

where t_0 ($\sim J/k_B \sim 10^{13}\text{s}$) is a microscopic time scale.³⁰ When we discuss the data below, we convert the actual duration of the perturbation $t_p(T_m + \Delta T)$ into the effective duration $t_e(T_m)$.

III. EXPERIMENTAL RESULTS

We focused on the relaxation rate of the magnetization, $S = (1/H)dM/d\log t$, measured under the various conditions of strength and duration of the perturbation.

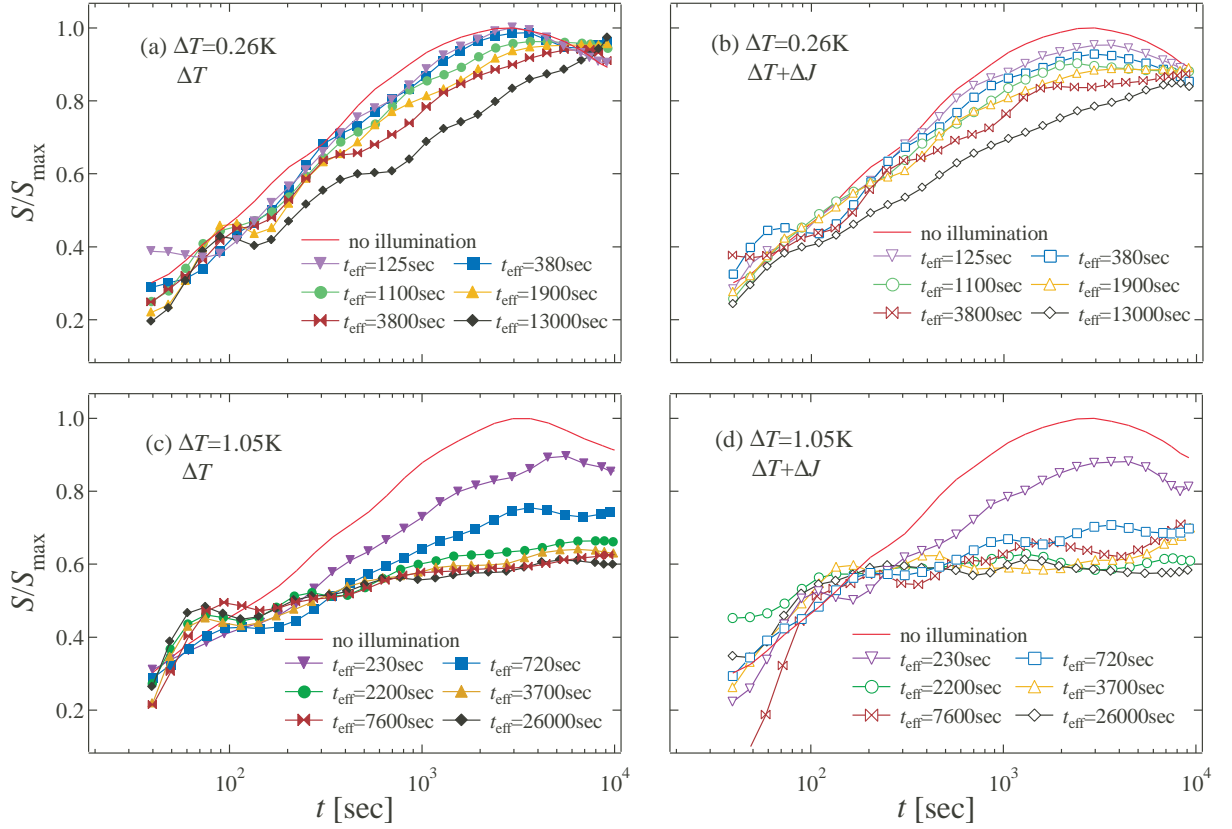

FIG. 3: (Color online) Time dependence of the relaxation rate S at 7K. Solid curves show S , measured after the waiting time $t_w = 3000$ s without illumination (isothermal aging). Figure (a) (filled symbol) and (b) (open symbol) show the relaxation rates S at various t_e for $T = 0.26$ K under T and $T + J$ perturbations, respectively. Figure (c) (filled symbol) and (d) (open symbol) show the relaxation rates S at various t_e for $T = 1.05$ K under T and $T + J$ perturbations, respectively. All the data are normalized by the maximum height of S without photo illumination.

Since we observed the peaks in the perturbation time-dependent data of S , the height of each peak and the corresponding peak position are important for our discussion.

The solid curves in FIG. 3 show the time dependence of the relaxation rate S , measured after the aging time $t_w = 3000$ s without illumination (isothermal aging). These curves show a peak at $t \approx 3000$ s, which is a typical behavior observed in many spin glasses.³¹

FIG. 3 also shows the typical data of perturbation time-dependent S at T_m ($= 7$ K) of the sample, where the constant temperature increment ΔT ($= 0.26$ K, 1.05 K) is added during t_e for the perturbation. The left figures (a) and (c) and the right figures (b) and (d) show the data under T and $T + J$ perturbations, respectively. All the data are normalized by the maximum height of S without photo illumination. In FIGs. 3(a) and 3(b) ($T = 0.26$ K), the peak in S at $t \approx t_w$ (we call this the main peak) becomes gradually depressed compared with the isothermal aging curve as t_e increases. The depression of S in FIG. 3(b) is more pronounced than that in FIG. 3(a) at the same t_e . In addition, the peak position in the main peak shifts to a longer time as t_e increases in both FIGs. 3(a) and 3(b). In FIGs. 3(c)

and 3(d) ($T = 1.05$ K), the main peak in S is depressed with increasing t_e in a more pronounced way compared with the data at $T = 0.26$ K. For long t_e , S becomes almost flat, but the main peak is incompletely erased. Furthermore, in FIGs. 3(c) and 3(d), a small peak appears around $t \approx 100$ s (we call this the sub peak) except for short t_e , and the sub-peak becomes more pronounced with increasing t_e . The sub-peak in FIG. 3(d) is less sensitive to t_e compared with that in FIG. 3(c). In FIG. 3(d), the sub-peak is so close to the main peak that the two peaks are insufficiently separable. We note that some curves in S in FIG. 3 show a sudden increase at large values of t (e.g., S for $t_e = 7600$ s in FIG. 3(d) (open symbols)). This may be due to a small fluctuation in the sample temperature.

IV. DISCUSSION

A. Theory based on the ghost domain scenario

Recently, aging behavior under the bond or temperature cycle has been explained based on the behavior of

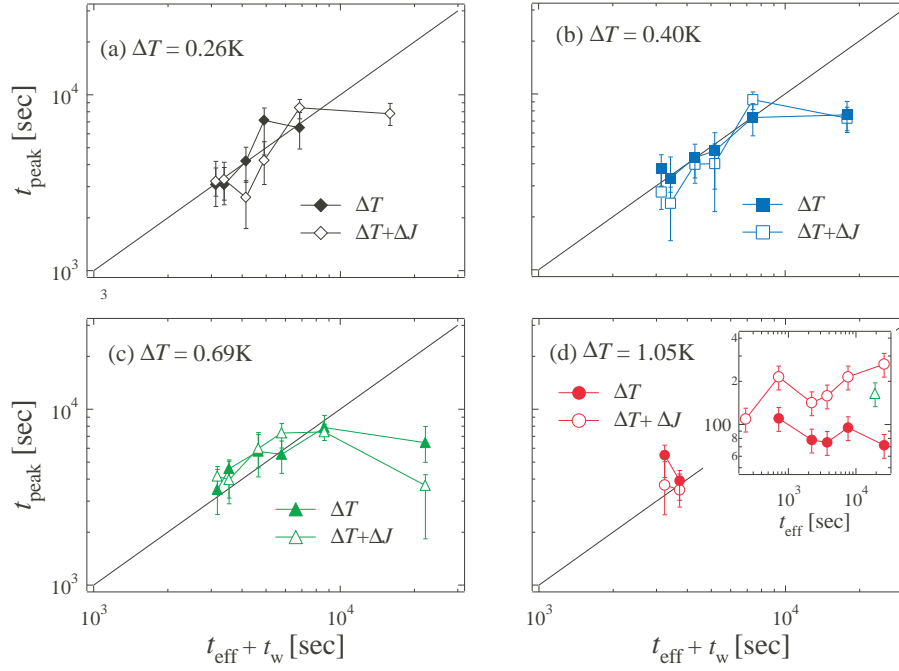

FIG. 4: (Color online) The $t_e + t_w$ dependent t_{peak} at various values of T . The increments of temperature under photo illumination, T , are 0.26K, 0.40K, 0.69K, 1.05K. Solid lines satisfies the equation $t_{\text{peak}} = t_w + t_e$. Filled symbols and open symbols show t_{peak} under T and $T + J$ perturbations, respectively. The inset shows t_e -dependent t_{peak}^0 . The symbols in the inset correspond to those in the main frame.

domains in terms of the ghost domain picture.^{10,11,12} In the following paragraphs, we interpret our results based on the behavior of the domain under the bond or temperature cycle in the same way. We divide our experimental protocol into three stages according to Fig. 2: the initial aging stage in which the equilibrium state A belongs to the environment A ($T_m; J$), the perturbation stage in which the equilibrium state B belongs to the new environment B ($T_m + T; J + \Delta J$), and the healing stage at the environment A .

In the initial aging stage, the domains belonging to A at T_m grow during t_w according to Eq. (1). In the perturbation stage, the perturbation X (T or $T + J$) is applied from t_w to $t_w + t_p$. During the perturbation stage, the "overlap" between the equilibrium states A and B disappears at the length scale beyond the overlap length L_X . The relation between L_X and the perturbation X is given as^{4,6}:

$$L_X = L_0 j^X = j^{1/\alpha} : \quad (4)$$

The chaos exponent is given by $\alpha = d_s = 2$ (> 0), where d_s is a fractal dimension and α is a stiffness exponent. Theoretically, temperature and bond perturbations are equivalent with respect to the overlap length L_X .¹¹

We can distinguish the weakly and strongly perturbed regimes based on the relationship between overlap length L_X and the domain size grown during each stages.^{11,12} If $L_{T_m + T}(t_p) < L_X$, a weakly perturbed regime appears, in which the rejuvenation scarcely emerges.⁹ If all the $L_{T_m}(t_w)$, $L_{T_m + T}(t_p)$, and $L_{T_m}(t)$ are greater

than L_X , a strongly perturbed regime appears, in which the initial spin configuration is unstable with respect to droplet excitation and a new equilibrium state appears. This suggests a chaotic nature. The chaos, however, does not appear abruptly^{7,8}, and there exists a crossover between the weakly and strongly perturbed regimes.

In the weakly perturbed regime, the domain belonging to A is weakly modified and the order parameter slowly decreases in the perturbation stage. The order parameter in the domains is easily recovered during the healing stage. Thus, the recovery time t_{rec} , which is necessary for the order parameter to saturate to 1, is given as

$$t_{\text{rec}}^{\text{weak}} : \quad (5)$$

In this regime, the size of domain belonging to A grows accumulatively so as to neglect the perturbation.

In the strongly perturbed regime, the spin configuration in domains belonging to A is completely random beyond the length scale of L_X , and the domains belonging to B grow during the perturbation stage. However, the effect of the initial domain of A remains as a ghost^{11,12}, i.e., the domains, that grow up to $L_{T_m}(t_w)$ during initial aging, can vaguely keep their overall shapes (which are called ghost domain), and the domain interiors are significantly modified due to the growth of domains B . Thus, the order parameter significantly decreases (but does not reach zero). When the perturbation is removed, the system recovers the initial spin configuration

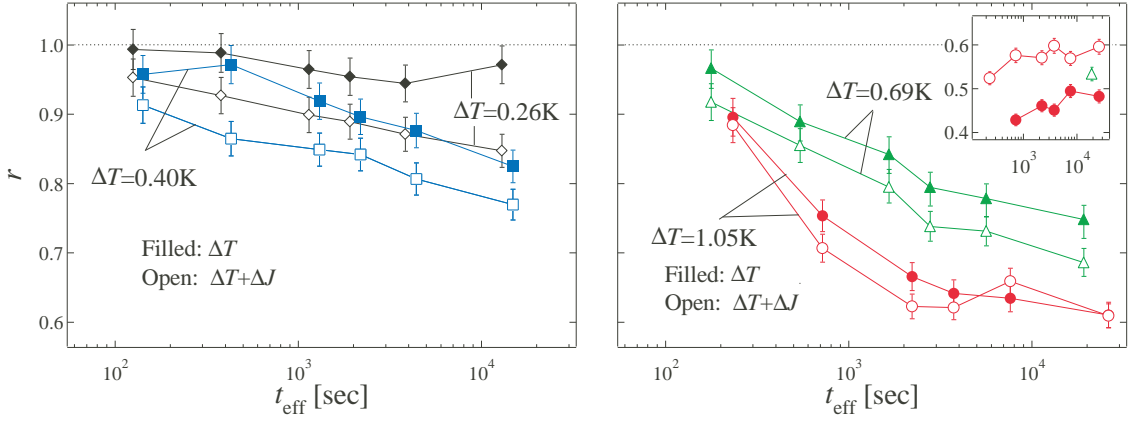

FIG. 5: (Color online) The t_e dependent r at various values of T . The increments of temperature under photo illumination, ΔT , are 0.26K, 0.40K, 0.69K and 1.05K. The filled and open symbols show r under T and $T + J$ perturbations, respectively. The inset shows t_e -dependent r^0 . The symbols in the inset correspond to those in the main frame.

(healing stage). The recovery time t_{rec} is given as

$$t_{rec}^{strong} : t_e : \quad (6)$$

In this regime, the domain belonging to A grows non-accumulatively.

B. The role of the relaxation rate under the cycling

The relaxation rate S is characterized under the temperature or bond perturbations shown in Sec. IV A, through the peak position and height in the time dependent S . First, we define the characteristic time t_{peak} corresponding to the position of the main peak. The value of t_{peak} is shown as a function of $t_e + t_w$ in FIG. 4D. If the aging is accumulative, the spin configuration at $T_m + T$ in the perturbation stage is equivalent to that under the isotherm aging at T_m for t_e . This results in the following relation:

$$t_{peak} = t_w + t_e ; \quad (7)$$

which corresponds to the reference line in FIG. 4. In the strongly perturbed regime ($L < L_x$), on the other hand, the chaotic nature becomes effective and the position of the main peak shifts to a shorter time compared with the accumulative aging curve. In this case, t_{peak} satisfies the relation,

$$t_{peak} < t_w + t_e : \quad (8)$$

During the healing stage, the order parameter of A starts to restore the domain structure grown during initial aging, and this is probably reflected in the height of the main peak. Thus, in order to characterize the change in the peak built in S , we define the relative peak height r , which is the ratio of the height in the main peak under the perturbation to that without perturbation. In

other words, r is the measure of the memory after the perturbation.¹² The value of r is shown as a function of t_e in FIG. 5.

In the completely weakly perturbed regime ($L_{T_m}(t_e) < L_x$), the order parameter fully recovers at t_{peak} according to Eq. (5). However, close to the strongly perturbed regime (the crossover regime between the weakly and strongly perturbed regimes), the order parameter does not completely recover at $t = t_w + t_e$. This leads to the decrease in the height of main peak. In the strongly perturbed regime, the order parameter insufficiently recovers because of the long recovery time t_{rec}^{strong} given in Eq. (6). Thus, r is gradually depressed as t_e increases because of the rapid increase in t_{rec}^{strong} . In addition, when the period t_s is necessary until the applied field is stabilized in a superconducting magnet after the perturbation is removed, the domain grows for t_s up to the size $L_{T_m}(t_s)$. This reflects the sub-peak.¹² Thus, the sub-peak becomes pronounced as the rejuvenation effects become clear.

C. Bond-cycling experiment

We try to classify our data, obtained under various perturbation conditions, into the following four categories: the weakly perturbed regime (we call this the W regime); the crossover regime, which is close to the weakly perturbed regime (we call this the WC regime); the crossover regime, which is close to the strongly perturbed regime (we call this the SC regime); and the strongly perturbed regime (we call this the S regime). The criteria for the classification are abridged in TABLE 1. The classification is mainly performed based on FIG. 4 and FIG. 5 in which t_{peak} and r are arranged as a function of t_e under various amplitudes of ΔT . The condition, i.e., t_e is variable and T is constant, corresponds to the situation that the domain size $L_{T_m}(t_e)$ grown during the perturbation stage is variable while the overlap

FIG. 6: (Color online) The T -dependent r at various values of t_e . Almost the same values of t_e are gathered together in one graph. The left, middle, and right figures show r under $t_e \sim 170$ and 520 s, $t_e \sim 1400$ and 2300 s, and $t_e \sim 4400$ and 18000 s, respectively. The filled and open symbols show r under T and $T + J$ perturbations, respectively.

lengths L_T and L_{T+J} are constant. In addition, we also pay attention to the sub-peak whose position and relative height are shown as t_{peak}^0 and r^0 in the insets in FIG. 4 (d) and FIG. 5 (b), respectively.

First we pay attention to the data at $T = 0.26$ K under T perturbation. As shown in FIG. 4 (a), the values of t_{peak} almost merge into the reference curve except for the data at the longest $t_e + t_w$, where the main peak for the longest t_e should appear at time much longer than the present observation time window ($\sim 10^4$ s). The sub-peak cannot be observed, and r scarcely decreases from 1 (FIG. 5). Therefore, all the data at $T = 0.26$ K under T perturbation satisfy the criteria for the W regime in Table I. Thus, the accumulative aging proceeds in this condition.

Under the J perturbation in addition to $T = 0.26$ K, the t_{peak} except for the longest t_e satisfies Eq. (7), and the t_{peak} at the longest t_e is shorter than $t_w + t_e$ (FIG. 4 (a)). The value of r clearly decreases from 1 except for the shortest t_e (FIG. 5). This indicates that J perturbation decreases the overlap length according to Eq. (4). Under $T + J$ perturbation with $T = 0.26$ K, thus, the system is not completely in the W regime except for the shortest t_e , and the chaotic nature partially emerges. Thus, this regime is in the WC regime except for the shortest t_e , at which the system belongs to the W regime.

Under both the perturbations with $T = 0.40$ K (see Fig. 4 (b)), the values of t_{peak} almost merge into the reference curve except for the data at the longest $t_e + t_w$. At the longest $t_e + t_w$, the values of t_{peak} under both the perturbations merge together, but lie below the reference curve. Under T perturbation, r is clearly lower than 1 except for the small t_e , while r under $T + J$ perturbation is clearly lower than 1 over all range of t_e (FIG. 5). The sub-peak cannot be observed under either perturbations. Therefore, at $T = 0.40$ K under the T perturbation, the system belongs to the WC regime except for short t_e , at which the system belongs to the W regime. Under the $T + J$ perturbation, the system belongs to the WC regime.

Next, we turn to the data under the strongest perturbation ($T = 1.05$ K) prior to the discussion of complex behavior under the medium perturbation ($T = 0.69$ K). At $T = 1.05$ K, t_{peak} cannot be determined at $T = 1.05$ K because the S curves are so attenuated except for the short t_e (see FIG. 4 (d)). The value of r rapidly decreases as t_e increases and becomes almost constant in the long t_e region, in which r under both the perturbations merge (FIG. 5). The sub-peak under T perturbation is observed except for the shortest t_e and becomes pronounced with increasing t_e (see the inset of FIG. 5). In the strongly perturbed regime, the chaotic effect significantly emerges and the main peak satisfies Eq. (8). In addition, the sub-peak, which is attributed to the rejuvenation, is observed around the time necessary to stabilize the applied field, i.e., $t_s \sim 100$ s. Under the perturbation with $T = 1.05$ K, thus, the system at long t_e may be in the S regime, where the order parameter becomes saturated to a level common to both kinds of perturbations and the rejuvenation effect becomes noticeable. Except for the long t_e , the system would not necessarily be classified into the S regime, because r is not saturated although the sub-peak is observable. Therefore, this system may belong to the SC regime. The system at the shortest t_e under T perturbation is classified into the WC regime because of the absence of the sub-peak.

At $T = 0.69$ K, t_{peak} almost merges into the reference curve except for the data at the longest $t_e + t_w$. At the longest t_e , however, the t_{peak} under $T + J$ perturbation is shorter than that under T perturbation. Moreover, the sub-peak appears under $T + J$ perturbation only at the longest t_e (see the inset of FIG. 4). Under both the perturbations with $T = 0.69$ K, r rapidly decreases from 1 as t_e increases, but does not become saturated (FIG. 5). Under the $T + J$ perturbation with $T = 0.69$ K, thus, the system at the longest t_e gets into the SC regime, whereas it does not under the T perturbation. Under the T perturbation with $T = 0.69$ K, the system belongs to the WC regime except for the shortest observation time, at which it belongs to the W regime because r scarcely deviates from 1.

To clearly evaluate the overlap length under both the perturbations, r is abridged under the condition that t_e is constant and T is variable (FIG. 6). This mirrors the situation that the domain size grown during the perturbation stage is fixed while the overlap length $L_{T+(J)}$ is varied. At the shortest t_e (~ 170 s) under T perturbation, r scarcely deviates from 1 as T increases. This indicates that τ_{rec} is so short that the order parameter in ghost domains easily recovers. At long t_e , r rapidly decreases as T increases. This shows the crossover from the weakly to the strongly perturbed regimes through the decrease in the overlap length. The values of r are smaller under $T+J$ perturbation than under T perturbation, but the difference in r between the perturbations becomes indistinct as T increases. Ultimately it disappears at large T due to the extremely long recovery time.

TABLE I: The definition of classification of our data under various perturbation conditions. (1) The condition $t_{peak} = t_e + t_w$ is satisfied. (2) Sub peak is observed. (3) The condition $r \geq 1$ is satisfied. (4) The value of r attains the saturation value. For example, the data that belongs to the W regime satisfy the condition (1) and (3), does not satisfy (2) and (4).

Regime	(1)	(2)	(3)	(4)
W	Y	N	Y	N
WC	Y	N	N	N
SC	Y	Y	N	N
S	N	Y	N	Y

FIG. 7 shows a schematic phase diagram in which the perturbation conditions are classified into the four regimes. In this figure, the boundary curves are guides to help the eyes grasp the qualitative aspect. As t_e and T increase, a systematic change from the W to the S regime is observed in the case of both the T and $T+J$ perturbations. In FIG. 7, we find a feature in which the boundary curve in the $T+J$ perturbation data lies below the corresponding boundary curve in the T perturbation data. This can be interpreted in terms of the decrease in the overlap length due to the additional perturbation J .

D. The effect of the bond perturbation

The order parameter under $T+J$ perturbation are smaller than those under T perturbation with the same T as mentioned above. These indicate that J perturbation decreases the order parameter through the decrease in the overlap length. This is clearly demonstrated in FIG. 7 through the shift of boundary curves. The behavior of the sub-peak, observed under both perturbations with $T = 1.05$ K, suggests that the rejuvenation effect becomes pronounced due to the additional J , because the t_{peak}^0 is longer and r^0 is larger under the

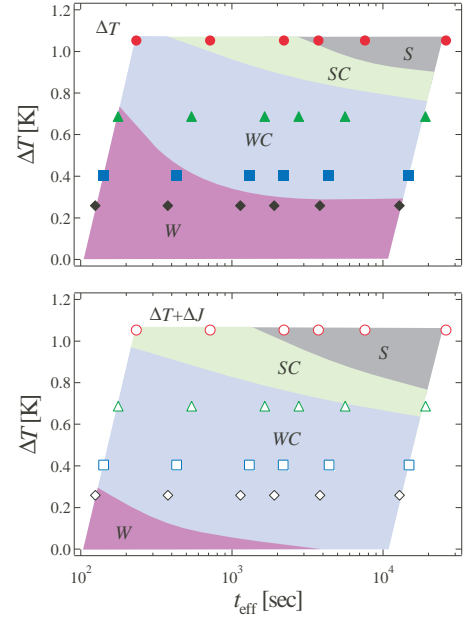

FIG. 7: (Color online) Schematic phase diagram where our data are classified into the four regimes: the weakly perturbed regime (W regime); the crossover regime (WC regime), which is close to the weakly perturbed regime; the crossover regime (SC regime), which is close to the strongly perturbed regime (S regime) (bottom to top). The upper and lower figures show the diagram under T and $T+J$ perturbations, respectively.

$T+J$ perturbation than under the T perturbation (see the inset of FIG. 4(d) and FIG. 5).

In addition, we pay attention to the feature in which r under $T+J$ perturbation with $T = 0.26$ K is significantly smaller than 1 while r under T perturbation is practically equal to 1 as t_e approaches zero, as shown in FIG. 5. This suggests that the J perturbation decreases the order parameter whereas the T perturbation does not, even at infinitesimally small t_e . Thus, at $T = 0.26$ K, the effect of T perturbation on the order parameter is so small that the J perturbation makes the dominant contribution. Based on the feature in which r under $T+J$ perturbation with $T = 0.26$ K is practically equal to that under T perturbation at $T = 0.40$ K, we estimate that $J = 0.14 - 0.40$ K at $T = 0.26$ K.

V. CONCLUSION

The bond perturbation J , under photo illumination, affects the aging behavior of semiconductor spin glass. We then estimated that $J = 0.14 - 0.40$ K at $T = 0.26$ K. Thus, the bond perturbation J can significantly change the bond configuration, although the photo-induced magnetization in $\text{Cd}_{0.63}\text{Mn}_{0.37}\text{Te}$ is negligible small.²⁸ This effect cannot be explained in terms of the strong separation of the time scales on different length scales. We attribute it to the decrease in the over-

lap length, i.e. $L_{T+\Delta T} < L_T$. Furthermore, we observed the crossover from weakly to strongly perturbed regimes in the bond cycling accompanied by the temperature cycling. These experimental results strongly suggest that "chaos" and the overlap length, which are the key concepts in the droplet picture, exist because the contribution of bond perturbation appears only in the overlap length.

In the future, it will be necessary to conduct the "pure" bond cycling experiment under photo illumination where there is no change in temperature. In addition, the mech-

anism of the bond perturbation using photo illumination should be clarified.

 - ²⁹ As shown in Fig.1, the FC susceptibility increases as temperature decreases, which is different from the conventional spin glass behavior. This is attributed to the paramagnetic contribution from the small magnetic clusters, which are not belonging to the freezing spins. See Ref.22.
 - ³⁰ The typical spin-flip time τ_0 in spin glass has been evaluated 10^{-13} s, e.g., 10^{-12} – 10^{-14} s for $\text{Cd}_{0.6}\text{Mn}_{0.4}\text{Te}$ and 10^{-12} – 10^{-15} s for $\text{Cd}_{0.55}\text{Mn}_{0.45}\text{Te}$ are evaluated [See A. Mauger et al., *Phys. Rev. B* **37**, 9022 (1988) and M. Saint-Paul and J. L. Tholence and W. G. Jiriat, *Solid State Commun.* **60**, 621 (1986)]. The duration of the perturbation is insensitive to the value of τ_0 , and we assume the typical spin-flip time of 10^{-13} s in the present work.
