We report a comprehensive infrared magneto-spectroscopy study of CeR  $u_4\,Sb_{12}$  compound revealing quasiparticles with heavy elective mass mass, with a detailed analysis of optical constants in elds up to 17 T. We note that the applied magnetic eld strongly a ects the low energy excitations in the system. In particular, the magnitude of magnetic eld strongly a ects the low energy excitations in the system. In particular, the magnitude of mass of

Systematic investigations of physical properties of Heavy Ferm ion (HF) materials have provided valuable insights into the role played by m any body e ects in transport and magnetic phenomena [1]. The HF ground state is believed to be a manifestation of a delicate balance between competing interactions [2]. External stimulican readily tip the balance yielding a variety of novel form s of matter. Motivated by the exceptional richness and complexity of e ects occurring in the HF systems under applied external stimuli, many research teams have undertaken the m ethodical investigation of properties under the variation of relevant control param eters, such as pressure (P) or magnetic eld (H) [3, 4, 5]. In this work we focused on the analysis of the low energy excitations of the HF system CeRu4Sb12 in high magnetic eldusing infrared (IR) spectroscopy. This technique has emerged as a very powerful experimental probe of the HF ground state [6, 7]. Essentially all hallmark features of the the HF state, such as the quasiparticle e ective massm, the optical gap , and a narrow D rude { like peak (with the width 1/) can be simultaneously studied based on the analysis of the optical constants.

Our IR magneto-optics results uncover robustness of the HF uid in CeRu<sub>4</sub>Sb<sub>12</sub> against magnetic eld: a eld of 17T suppresses the quasiparticle e ective mass by about 25%. The reason we selected CeRu4Sb12 for higheld investigations reported here is two-fold. First, the fam ily of skutterudite com pounds to which CeRu<sub>4</sub>Sb<sub>12</sub> belongs reveals a broad spectrum of behavior, including non-Ferm i liquid power laws, superconductivity with unconventional order param eter and antiferrom agnetism [8, 9, 10, 11]. This catalogue of enigm atic properties supports the notion of the competing ground states: a regime where even modest external stimuli are likely to have a major impact on the response of a system. Second, our earlier zero- eld experim ents have uncovered rem arkably large changes of re ectance R (!) of CeRu<sub>4</sub>Sb<sub>12</sub> at low tem peratures: the re ectance drops by more than 20% in the far-IR [7]. With such a strong feature, unprecedented

am ong HF com pounds, a task ofm on itoring subtle eld-induced modi cations of electrodynam ics is becoming a viable endeavor.

Sam ples of CeR  $u_4$ Sb<sub>12</sub> were synthesized using Sb{ ux m ethod with an excess of Sb (for m ore details on sam ple growth see Ref. 8). Large polycrystalline specimens with a typical surface area of 4  $4\,\mathrm{m\,m^2}$  were essential for m agneto{optical experiments. The sam ples have been characterized by resistivity and m agnetization m easurements and found to be of similar quality as previously reported [8].

The electrodynam ic response of CeRu<sub>4</sub>Sb<sub>12</sub> was studied using infrared and optical re ectance spectroscopy. Zero eld near{normal{incidence re ectance R (!) was m easured in the frequency range 30{30,000 cm <sup>1</sup> proximately  $4 \text{ m eV } \{4 \text{ eV}\}$  from T = 10 K to room tem perature. These m easurem ents were supplem ented with magneto{optic re ectance ratios R(!,H)/R(!,H=0T)obtained in zero { eld cooling conditions at 10 K [12]. The absolute value of re ectance in magnetic R (!, H) was obtained by multiplying these ratios with the H = 0 data R(!, H) = [R(!, H)/R(!, H = 0T)] R(!). The com plex optical conductivity  $(!) = _1(!) + i_2(!)$  and dielectric function  $(!) = _1(!) + i_2(!)$  were obtained from re ectance using Kramers (Kronig analysis. For low-frequency extrapolations, we used the Hagen-Rubens formula (thin line in Fig. 1). The overall uncertainty in (!) and (!) due to low-and high-frequency extrapolations required for K ram ers {K ronig analysis is about 8-10 %. This uncertainty does not a ect any conclusions of the paper in any signi cant way.

P lotted in the top panel of Fig.1 is the tem perature dependence of rejectance R (!) over an extended frequency interval. The gross features of R (!) are in good agreement with the spectra obtained previously on single crystals [7]. The general shape of the rejectance spectrum at 300 K is metallic, with high absolute values at low frequencies, and a well defined edge around  $4,000\,\mathrm{cm}^{-1}$  (not shown). Below a coherence temperature T which

is about 50 K for  $CeRu_4Sb_{12}$  [7] there is a strong suppression of rejectance in the range between 50 and 1,000 cm  $^1$ . This result is indicative of the development of a gap in the density of states commonly observed in HF systems. Simultaneously a new feature develops in the far-IR. This structure bears similarities with the conventional "plasma edge" in metals and is established as a spectroscopic signature of heavy quasiparticles [6]. The rejectance edge softens with decrease of T down to 60 cm  $^1$  in the 10 K spectra. Several narrow peaks in the far{IR region are due to optically active phonons and will be discussed below.

The bottom panel of Fig. 1 displays the re ectance data in magnetic eld, plotted on a linear scale over a narrower frequency interval in order to emphasize eldinduced changes. Only a few in-eld curves are shown for clarity. For comparison, the plot also includes several zero eld spectra at higher tem peratures. The thin line is a Hagen {Rubens extrapolation used for the 300 K spectrum. For elds below 5T no signi cant change in reectance can be detected, within the error bars of the experim ent. At higher elds, the frequency position of the low lying "plasm a edge" hardens, a behavior which is paralleled by zero-eld spectra taken at higher T. Com paring tem perature-and eld-induced modi cation of R (!), we notice that the net e ect of applying a 17 T eld is functionally equivalent to a temperature increase of At higher frequencies (!  $> 110 \, \text{cm}^{-1}$ ) the rejectance is eld independent for H < 17T, within the error bars of the present experim ent.

The top panel of Fig. 2 displays the tem perature dependence of the dissipative part of the optical conductivity  $_{1}$  (!). The dom inant feature in the low-T data is a sharp increase in the conductivity above  $80\,\mathrm{cm}^{-1}$ with an overshoot of the 300 K spectrum at  $550 \, \mathrm{cm}^{-1}$ . This behavior is usually assigned to the form ation of the (hybridization) gap in the excitation spectrum of a HF system [6]. Because of the improved signal-to-noise ratio, it becam e possible to extend earlier zero eld measurements [7] to lower frequencies. These new results allow us to resolve the onset of a narrow D rude-like feature, usually associated with the response of heavy quasiparticles at low T [6]. The gradual suppression of the conductivity at  $! < 60 \text{ cm}^{-1}$  at low T is consistent with the decrease of the quasiparticle scattering rate 1/ (!) below the low -! cut-o of our data (30 cm 1). The latter e ect will lead to an increase of the conductivity in the !! 0 lim it, in accord with the DC resistivity measurements [9, 10, 13] displayed with full symbols. The narrow resonances at 88, 116, 131, 205, 221 and 248 cm <sup>1</sup> are phonon modes. Some of these modes, including the peaks at 88, 131 and 205 cm<sup>-1</sup>, have not been observed before in m easurem ents on smaller single crystals [7]. W e also observe an additional mode at 40 cm 1 which can be identied only in the low-T spectra once the electronic background in the conductivity is dim in ished.

The bottom panel of Fig. 2 displays the optical conductivity  $_1$  (!) at 10 K in a magnetic eld, along with 30 K data (in zero eld). Only a limited frequency region is shown to emphasize the elects due to applied elds. We not that the onset of the gap structure in  $_1$  (!) is virtually unally unally extended even by the 17 Teld. On the other hand, the coherent mode due to heavy quasiparticles broadens as the eld increases. This is consistent with positive magneto-resistance in the DC data [9, 10, 13].

Field induced e ects in the optical constants can be quanti ed using several complementary methods. The extended D rude model (EDM) o ers an instructive analysis protocoland is routinely used to quantify correlation e ects in HF systems [6]. Within the EDM the optical constants are expressed in terms of the quasiparticle scattering rate 1= (!) and the ective mass spectrum m (!) [6]. Specically, m (!) can be obtained from the following equation:

$$\frac{m (!)}{m_{b}} = \frac{!_{p}^{2}}{4 !} \text{Im} \frac{h}{(!)} ; \qquad (1)$$

the plasm a frequency  $\overline{4 e^2 n} = m_b = 10,744 \text{ cm}^{-1}$  is estimated from the integration of  $_{1}(!)$  up to the frequency of the onset of interband absorption. The spectra of m (!) in HF compounds usually reveal a complicated frequency dependence which is particularly true in the vicinity of the energy gap [6]. However, an extrapolation of m (!) spectra towards zero frequency yields a reliable estim ate of the quasiparticle e ective mass m that has been shown to agree with the therm odynamic mass for a variety of HF compounds [6, 7]. The estimated value of '  $70 \, \text{m}_{\, \text{b}}$  (at  $10 \, \text{K}$  )  $C \, \text{eR} \, \text{u}_4 \, \text{Sb}_{12}$  is som ewhat smaller then previously reported 80 m b for single crystals [7]. This e ect can be assigned to increased disorder and/or variations of the K ondo temperature in polycrystalline specimens compared with previously studied single crystals. In the middle panel of Fig. 3 we plot the extracted values of the mass in zero frequency limit as a function of magnetic eld. A 17T eld is capable of suppressing the mass by about 25% from its zero-eld value.

A Itematively, mass renormalization can be inferred from the analysis of the loss function spectra Im [1/(!)] (top panelofFig.3). The loss function of ersa convenient way to explore longitudinalmodes in the optical spectra, including heavy electron plasmons in HF compounds [6]. These longitudinalmodes produce Lorentzian-like peaks in Im [1/(!)] spectra centered at  $!_p=\frac{1}{4}\frac{1}{e^2}n=\frac{1}{1}\frac{1}{m}$ , where  $_1$  is the high-frequency contribution to the dielectric function. In Fig. 3 the plasmon due to heavy quasiparticles is clearly observed at '74 cm  $^1$  at 10 K. A stem perature increases the plasmon shifts to higher energies, in plying a decrease of the quasiparticle elective mass (!  $_p=\frac{1}{m}$ ). Similarly, as the magnetic eld

increases, the mode hardens to 90 cm  $^1$ , which again indicates that the heavy quasiparticles reduce their effective mass. In the top panel of Fig. 3, we plot the eld dependence of the mass determined from the frequency of the peak in the loss function spectra. In full agreement with the values obtained by extrapolating m (!) spectra to zero frequency, we observe a marked depression of the elective mass by nearly 25% at 17T, with the characteristic downward curvature.

We have also employed two additional methods of quantifying the eld-induced changes of m. The simplest estimate of renormalization is the (inverse of the) position of the minimum in relectance. The minimum in relectance, the so-called plasmaminimum, is determined by the screen plasma frequency, which on the other hand is proportional to the ratio n=m, where n is the carrier density and method their elective mass. The plasmaminimum points (from Fig. 1) are also plotted in the middle panel of Fig. 3 and they agree well with previous two data sets. Finally the partial sum rule:

$$Z_{!c}$$
<sub>1</sub> (!)d! =  $\frac{(!p)^2}{8} = \frac{ne^2}{2m}$ ; (2)

can also give an estim ate of the e ective m ass [6]. The upper integration lim it  $!_{\rm c}$  was set just below the onset of hybridiztion gap. The values of the e ective m ass extracted this way are also in good agreement with the other three m ethods (Fig. 3, m iddle panel). The scatter of data points in Fig. 3 serves as an estimate of the error bars.

The Periodic Anderson Model (PAM) is believed to capture the essence of the physics in HF m etals [1]. W e will show below that this model when augmented with the Zeem an term elucidates the behavior of the e ective mass in a magnetic eld. At the mean-eld level, the heavy ferm ion state is characterized by hybridization of the free (c) and localized (f) electrons [14, 15]. Hybridization breaks the conduction band into disjoint upper and lower branches with very shallow dispersion near the gap edge (Fig. 3 bottom panel); this accounts for the very large e ective m ass of the quasiparticles. The state ism etallic and possesses a well-de ned Ferm i surface that incorporates both the c and f electrons. In the presence of a Zeem an term { which consists of a magnetic eld AT coupled to the total magnetic moment at each site { the m ass enhancem ent factor behaves as [16]:

$$\frac{m}{m_{e}} = \frac{m}{m_{e}} + 1 + 2s + \frac{H}{H_{0}} + \frac{3}{2} + \frac{H}{H_{0}}^{2}; \quad (3)$$

where m $_{\rm e}$  is the free electron mass, s = (";#) and H $_{\rm 0}$  is on the order of the Kondo energy in magnetic units. The linear term in Eq. 3 results from the splitting of the Ferm i surface into separate spin-up and spindown surfaces, each with a dierent band curvature. The

quadratic term is due to higher-order changes in the hybridization energy.

The quasiparticle contribution to the optical conductivity (!) of the Zeem an-split heavy electron m etal is:

$$(!) = \frac{e^2}{m_e} \frac{X}{1 = \frac{n_s}{1 + (m_e)_s}}; \qquad (4)$$

where 1= is the quasiparticle scattering rate. The quasiparticles have a total density  $n=n_{"}+n_{\#}=n_{c}+n_{f}$ ; in a Zeem an eld, they are spin-polarized according to  $n_{"}-n_{\#}=H=H_{0}$ . In the lim it! 1, Eqs. 3 and 4 can be combined to give:

$$\frac{!\frac{2}{p}}{4!} \operatorname{Im} \frac{h}{(!)} = \frac{m}{m_{e}} = 1 + \frac{5}{2} + \frac{2n_{f}}{n} + \frac{H}{H_{0}}^{2};$$
(5)

which for H = 0T reduces to Eq. 1. According to Eq. 5, the e ective mass probed in an IR experiment is averaged between the two spin channels and its magnitude is reduced as  $(H/H_0)^2$ , in full agreement with the experim ental observation (top panel of Fig. 3). The t (gray line) corresponds to  $H_0 = 35 \,\mathrm{T}$  . This estim at of  $H_0$ is lower then the K ondo temperature  $T_K$  ' 100K [10] for CeRu<sub>4</sub>Sb<sub>12</sub> but is close to the coherence tem perature T ' 50 K. The Zeem an splitting also implies an overall reduction of the energy gap between the spin-down subband at E > E  $_{\rm F}$  and the spin-up sub-band at E < E  $_{\rm F}$ [16]. As pointed out above, appreciable reduction of the gap is not observed in our data. This is consistent with the notion that in an optical experim ent one probes separately gaps in the spin-up and spin-down channels, provided that spin ip scattering does not signi cantly alter the selection rules. Neither of the two transitions is expected to signi cantly change in elds smaller than the hybridization gap. Further theoretical studies are needed to address the issue of spin- ip scattering, as well as the problem of the eld dependence of the hybridization en-

In conclusion, we have presented a comprehensive set of infrared data obtained on  $C\,eR\,u_4\,Sb_{12}$  in high magnetic eld. The external eld is found to a ect the low-energy excitations of the system, which leads to the renormalization of the quasiparticle elective mass. Indeed, a 17 T eld was found to diminish m by about 25%. Meaneld solution of the PAM with a Zeeman term o ers a quantitative account for the eld dependence of the elective mass.
