Universal tem perature dependence of the conductivity of a strongly disordered granular metal

A.R.Akhmerov, A.S.Ioselevich, L.D.Landau Institute for Theoretical Physics, 119334 Moscow, Kosygina 2, Russia (Dated: January 15, 2022)

A disordered array of metal grains with large and random intergrain conductances is studied within the one-loop accuracy renormalization group approach. While at low level of disorder the dependence of conductivity on log T is nonuniversal (it depends on details of the array's geometry), for strong disorder this dependence is described by a universal nonlinear function, which depends only on the array's dimensionality. In two dimensions this function is found numerically. The dimensional crossover in granular In s is discussed.

Introduction. Unusual temperature dependence of conductivity of granular metals has been in the focus of both experimental (see, e.g., [1, 2, 3] and references therein) and theoretical [4, 5, 6, 7, 8, 9, 10, 11, 12, 13] studies in recent years. In particular, the logarithm ic T-dependence of resistivity

$$= A (1 ln T); (1)$$

was experimentally established in [2] for low-resistivity samples, while high resistivity samples, studied by the same group, demonstrated the characteristic E fros-Shklovskiilaw / expf ($T_{\rm ES}=T$) $^{1=2}$ g (see [10,12] for theoretical interpretation). The empiric dependence (1) was found to be valid in the wide T-range 30-300 K, where the resistivity varied by a factor of order 3.

A similar weak T-dependence of low-resistivity granular lms was observed also in [3]. Although in [3] this dependence was interpreted as a power-law = AT with small = 0:117, it could with the same accuracy be tted by the law (1).

The dependence (1) can not be explained by the usual weak-localization e ects because of many reasons. In particular, the dependence (1) was apparently found in both two-and three-dimensional samples, and, secondly, it appears to be insensitive to the magnetic eld.

The logarithm ic T-dependence of the conductivity (not the resistivity!) was theoretically derived by E fetov and T schersich [4]. It arises due to corrections to conductivity, originating from local quantum uctuations of intergrain voltages, a la Ambegaokar, Eckem, and Schon [14]. Under the conditions g_0 1 (low resistivity at high temperature) and g_0 T E_C (moderately low temperature), E fetov and T schersich have found that

$$\frac{\text{(T)}}{\text{(T_R)}} = 1 \quad \frac{4}{2g_0} \ln \frac{T_R}{T}$$
 (2)

for an ideal lattice of identical grains with identical intergrain conductances. Here g_0 is the dimensionless (measured in the units of $e^2=2\,$ ~) intergrain conductance at

high temperature T $$T_{\rm R}=g_0E_{\rm C}$$, is the intragrain level spacing, z is the coordination number of the lattice, and E_C is the charging energy of an individual grain. Note, that $_{\rm R}$ ~= $T_{\rm R}$ is nothing else, but the characteristic local charge relaxation time in the system . The formula (2) is valid for a lattice of arbitrary dimensionality.

Later, in the paper [8] the theory of E fetov and T schersich was generalized for the case of nonideal { random { array of m etal grains. It was shown, that the system of one-loop RG equations, describing the renorm alization of individual intergrain conductances g_{ij} upon lowering of tem perature, can be written in the form

$$\frac{d \ln g_{ij}}{dt} = 2R_{ij} (fg_{kl}g); \qquad (3)$$

where t $\,$ ln (T $_{\!\!R}$ =T) { is the \RG time", and R $_{ij}$ are dimensionless resistances of the entire network between the grains i and j. These resistances are some complicated nonlocal functions of all the conductances in the array; to nd them one rst would have to solve the set of the K irchhof equations

$$X = g_{k1} V_k^{(ij)} = V_1^{(ij)} = ik jk;$$
 (4)

for voltages $V_k^{(ij)}$, and then $\,$ nd R $_{ij}$ (fg_klg) = $V_i^{(ij)}$ V $_j^{(ij)}$. This task is analytically not feasible for general random inhomogeneous network of conductances.

For the case of weak disorder it was shown in [8] that the theoretical dependence of on ln T considerably deviates from the linear law (2) only in the vicinity of the metal-insulator transition, where the role of disorder becomes crucial. In the major part of the domain of the applicability of the one-loop RG approach the Efetov-T schersich law (2) remains a good approximation even for a moderately strong disorder, when the relative uctuations of intergrain conductances are of order of unity. At least this is true for the case of square lattice, which was studied numerically in [8].

In the present Letter we are considering the case of extrem ely strong disorder. This study is motivated by

two reasons. First, the E fetov-T schersich linear law (2) for the conductivity is by no means identical to the experimentally observed linear law (1) for resistivity. It is important to understand, if the deviations from the law (2) due to the disorder can explain this discrepancy between theory and experiment.

Secondly, one can expect inhom ogeneous uctuations of g_{ij} to be indeed very strong. The intergrain conductance g_{ij} exponentially depends on the thickness d_{ij} of an insulating layer between the grains

$$g_{ij} = \overline{g}_0 e^{h_{ij}}; \quad h_{ij} = 2 (d_{ij} \text{ hdi}); \quad (5)$$

where \overline{g}_0 exphln gi. The decrement of the electronic wave-function within the insulating layer 1 5A 1 , so that already uctuations of d_{ij} with quite moderate standard deviation of order of few Angstromsm ay cause gigantic uctuations of g_{ij} . Thus, the condition of strong uctuations

$$p \frac{1}{hh^2 i} 1$$
 (6)

can be ful lled very easily.

C ritical networks. Under the condition (6) neither the perturbation theory, nor the elective medium approximation, used, respectively, in the case of weak and moderately strong disorder in [8], can provide a reliable tool for nding the conductivity of the system. One can use instead the theory of highly inhomogeneous media (see, e.g., [15, 16]). A coording to this theory, the conductivity of highly inhomogeneous network of conductances is determined by the so called critical subnetwork, constructed according to the following recipe (we will call it the \q-procedure"):

The critical conductance $g=\overline{g}e^{h_{\text{c}}}$ is found from the condition

$$Z_{1}$$
 $P(h)dh = p_{c};$
(7)

where P (h) is the distribution function of h (we assume that there is no correlation between conductances of dierent contacts), p_c is the percolation threshold for the \bonds problem " on a lattice of granules (regular, or irregular { depending on the geometry of the array).

Certain number q is chosen, such that $1^{<}$ q.

All the intergrain contacts with $h_j < h_c$ q are substituted by in nite resistances (disconnected).

The contacts with $h_j > h_c + q$ are substituted by ideal conductances (abridged). Thus, the entire set of granules falls apart into a number of nite clusters, all members of the same cluster being ideally connected. These clusters serve as vertices n in the elective network.

FIG.1: A fragment of a critical network $C_{q=1:7}^{(2)}$, corresponding to a particular random conductance network with = 8:66 on a square lattice 140 140. The vertices (clusters) are shown as black circles, a thickness of a bond between two vertices $n; n^0$ is proportional to the connection number N_{nn^0} .

The \critical conductances" with the hij < q can either connect granules within the same cluster n (then they are shunted by ideal conductors and can be discarded), or establish links between different clusters n and n⁰. Thus, we arrive at an e ective network of vertices n, some of them being connected by critical conductances. There may be more than one critical conductance, connecting the same pair of vertices. By construction (because $h_c + q > h_c$), besides nite fragments, there must be also an in nite connected subnetwork in this e ective network, spanning through the entire system. As usual, one can cut o all \dangling ends" of this in nite subnetwork and thus extract the backbone, which is the substructure, relevant for the dc conductivity (for the consistent de nition of the backbone and the dangling ends, see, e.g., [17]). It is this backbone, that we will call the d-dim ensional critical network $\boldsymbol{C}_q^{(d)}$ of width q. A fragm ent of a typical computer-simulated critical network is shown in Fig.1.

Finally we are left with a random multiply connected network, in which every conductance is an independent random variable. The geometry of this network is highly

FIG. 2: The probability distributions for coordination numbers z and connection numbers z for the same critical network, as in Fig.1.

nontrivial. D istribution functions for coordination numbers z_n , and for the \connection numbers" N_{nn^0} (numbers of critical conductances, connecting vertices n and n^0) are shown in Fig.2. It should be noted that z_n at dierent vertices, as well as N_{nn^0} at dierent links, are correlated, because vertices, corresponding to larger clusters of abridged grains, have a tendency to both larger coordination and larger connection numbers.

The statistical geometry of the critical network, no matter how complicated, is universal: it depends neither on details of the initial lattice of grains, nor on the distribution function of individual conductances. Topological properties of critical networks for all systems of a given spatial dimension dare statistically equivalent. Dierent critical networks within the same universality class dier from each other only in the spatial scale { the correlation radius (see [16]):

$$^{(d)} = a P (h_c)]^{-d} a^{-d};$$
 (8)

where a is the typical intergrain distance, $_{\rm d}$ is the critical exponent of the correlation radius for the percolation problem in d dimensions ($_2$ = 4=3 and $_3$ 0:875, see [17]). The conductivity of the critical network is

$$q = \frac{e^{2}}{2 \sim A_{q}^{(d)} g_{c}} A_{q}^{(d)} g_{c}^{h} \frac{i_{2} d}{2 \sim a^{d}} \frac{e^{2} a^{2} d}{2 \sim a^{d}} \overline{g}_{0}^{d} e^{h_{c}};$$
(9)

where $A_q^{(d)}$ is a num erical prefactor.

Since the critical network $C_q^{(d)}$ explicitly depends on the value of the parameter q, so does the corresponding conductivity $_q$. To get physically relevant $_{q!\ 1}$ one has, in principle, to extrapolate the result to q 1. Fortunately, already for q > 1 the value of q a ects only the numerical preexponential factor $A_q^{(d)}$, which rapidly converges to the true value $A_q^{(d)}$ as q grows (the corrections

are exponentially small at q=1). The conductances with $h_{ij}=h_{e}j=1$ do not play any considerable role in the critical subnetwork, therefore for a qualitative discussion it is su cient to choose some q=1 and not to bother much about the elects of nite q. These weak and purely quantitative elects will be discussed below, when we will compare the numerical results, obtained for different values of q.

Tem perature dependence of the critical network's conductivity. In our problem the conductivity is also determined by the critical network, but the conductances in this network evolve with \RG time" t according to the RG equations

$$\frac{d \ln g_{nn^0}^{(k)}}{dt} = 2R_{nn^0};$$
 (10)

where index $k=1;:::;N_{nn^0}$ distinguishes di erent conductances, connecting the same pair nn^0 of vertices; R_{nn^0} is the resistance of the critical network between vertices n and n^0 . It is very important, that these resistances are governed solely by the critical conductances, so that the system (10) is closed.

Let us introduce normalized variables

$$y_{nn^0}^{(k)} = h_{nn^0}^{(k)} \quad h_e; \quad t = \frac{t}{A^{(d)}g_c}; \quad \sim = \frac{h}{A^{(d)}g_c} \frac{i_{d}^2}{e^2};$$
(11)

then

The critical network is reduced to a completely universal one, with the spatial scale equal to unity.

The equations 3) take the universal form

$$\frac{dy_{nn^0}^{(k)}}{dt} = 2A^{(d)}\tilde{R}_{nn^0} e^{y_{11^0}^{(p)}}$$
 (12)

Initial conditions $y_{n}^{(k)}$ (t=0) for the RG equations (12) independently take random values with a universal distribution function

$$P_{q}(y) = \frac{(q + y)}{2\alpha}; \qquad (13)$$

Thus we have arrived at a completely universal mathematical problem: One has to solve a set of universal equations (with universal initial conditions) for variables $y_{nn^0}^{(k)}$, de ned on a random graph with universal statistical properties. As a result, the normalized conductivity \sim should be a universal function of the normalized time for

$$\sim_{\mathbf{q}} = \mathbf{F}_{\mathbf{q}}^{(d)}$$
 (t); (14)

the shape of this function depends only on the space dimensionality d and on the parameter q. At q > 1 the q dependence is very weak and can be neglected, therefore

we om it the index q in what follows. Unfortunately, we were not able to nd this universal function analytically, so we had to do that num erically (see below).

Coming back to the initial physical variables, we get the global conductivity of the system in the form:

$$\frac{\text{(T)}}{\text{(T_R)}} = F^{\text{(d)}} \frac{e^2 = 2 \sim}{e^{2} = 2 (T_R)} \ln \frac{T_R}{T}; \quad (15)$$

where T_R g_*E_C . The only nonuniversal (i.e., depending on the details of the conductances' distribution function) ingredient in this formula is $^{(d)}$ d . Note also, that there is absolutely no reminiscence of the nonuniversal short-scale geometric structure of the array.

Lateral conductance of granular lm s. One should distinguish between thin lm s, whose thickness L $^{(3)}$, and thick lm s with L $^{(3)}$. The arguments of paper [18] (see also book [16]), designed for the description of hopping conductivity in lm s, can be modiled for our case. The true 3-dimensional behavior takes place only in thick lm s, where the dimensionless conductance of a square sheet of the $lm is G = ^{(3)} L$, and

$$\frac{G \quad (T)}{G \quad (T_R)} = F^{(3)} \qquad \frac{L}{G} \qquad \frac{\ln (T_R = T)}{G \quad (T_R)} \quad : \tag{16}$$

Forthin lms

$$\frac{G \quad (T)}{G \quad (T_R)} = F^{(2)} \quad \frac{\ln (T_R = T)}{G \quad (T_R)} \quad ; \tag{17}$$

and G exponentially depends on L:

G
$$(T_R) = A^{(d)} \overline{g}_0 e^{h_c(L)};$$
 (18)

where $h_{\rm c}$ = $h_{\rm c}$ (L) is determined as a threshold of lateral percolation in a slab of thickness $\,L\,$ cut out of a three-dimensional network of all conductances with $h_{ij} < h_{\rm c}$. The threshold condition has a form

$$^{(3)}(h_c) = c L;$$
 (19)

where the three-dimensional correlation length $^{(3)}$ (h_c) a [(h_c) h_c)=] 3 , and c 1. As a result, in the range a L $^{(3)}$ one nds

$$h_c^{(3)}$$
 $h_c(L) = D$ (a= L) ^{1= 3}; (20)

where D is some nonuniversal numerical constant (see [16]). Note, that this formula interpolates between $h_{\rm c}^{(3)}$ in the case of a bulk, thick $\,$ lm , and $h_{\rm c}^{(2)}$ in the case of a one-m onolayer $\,$ lm .

The quasi two-dim ensional critical network $C_q^{(2)}$, arising in the lm as a result of the q-procedure, centered at h_c (L), is characterized by the elective two-dim ensional correlation length $_e^{(2)}$. To estimate this length we write it in a form $_e^{(2)} = a$ (L=a) $_e^{1} = a$, which follows from

the scaling arguments. This expression, valid in the range a L $^{(3)}$, should m atch with the true two-dimensional behavior $_{\rm e}^{(2)}=^{(2)}$ 2 at L a, and with the true three-dimensional one $_{\rm e}^{(2)}=^{(3)}$ 3 at L $^{(3)}$. These two matching conditions x the exponents $_1$; $_2$, so that we nd $_1$ = 1 ($_2$ = $_3$) and $_2$ = $_2$. As a result, $_{\rm e}^{(2)}$ can be conveniently written in a form

$$_{\rm e}^{(2)}$$
 L $^{(3)}=$ L $^{^{2}=~_3}$ L: (21)

Thus, our quasi-two-dim ensional critical network is indeed e ectively strictly two-dim ensional, hence it belongs to the corresponding d=2 universality class, and the universal function is $F^{(2)}$ for all m s w ith $L^{(3)}$ (cf. formula (17)), not only for those, consisting of just one m on olayer of grains.

Num erical results. In this Letter we present the num erical results only for the two-dim ensional case. For determination of the function $F_q^{(2)}(t)$ we have generated random L L square arrays of conductances with $\frac{1}{3}$ $\frac{1}{3}$ for diexent distribution P (h) = $(\frac{1}{3})$ 20 < L < 140 and 0 < < 8:66. For the samples with large we constructed critical networks C q with 0:5 < q < 2, and num erically solved the system of equations (12) and (4) on these networks, which are very much sm aller arrays, than the initial ones. Note, that only due to this truncation of the array, as well as to the fact, that the conductances of the critical network are all of the same order of magnitude, the problem becomes feasible. The num erical solution of the full set of K irchhof equations for a reasonably large array of strongly di erent conductances would be practically im possible. Thus, the concept of the critical network turns out to be crucially helpful not only for understanding of basic physics, but also for the num erics.

The main result { the dependence of the conductivity on $\ln (T_R = T)$ for dierent values of is shown in Fig. 3. One can see that this dependence becomes universal already at 3 4: the di erence between curves with = 3:47 and = 8:66 is negligible, so we can with reasonably high accuracy identify the last one with the universal function F $^{(2)}$ (t). In the range 0 < t < 0.5 it is approximately linear with a slope, corresponding to an e ective coordination number ze 32, which is consistent with the statistics of coordination, shown in Fig 2. Note, that z_e is universal and does not depend on the coordination number z of the initial lattice. At t> 0:5 the slope starts to decrease rapidly, and F (2) (t) goes to zero at to 12. Unfortunately, the problem of nding the critical exponent, which characterizes the behavior of $F^{(2)}$ (t) at t! t_c , seem s to be num errically not feasible.

We also have checked the accuracy of the method from the point of view of nite size and nite q corrections. For an array 40 40 with = 1.734 we were able to

FIG. 3: Dependence of the normalized conductance per square for a thin $\,$ lm on the parameter t = $\,$ ln (T_R =T) for different standard deviations of the logarithm s of intergrain conductances. M is the number of samples in the averaging ensemble. In all cases q=1.7 and L $^{(2)}$ (). (a) { = 0.14, L = 50, M = 150; (b) { = 0.58, L = 50, M = 150; (c) { = 1.16, L = 50, M = 300; (d) { = 2.31, L = 80, M = 300; (e) { = 3.47, L = 100, M = 400; (f) { = 8.66, L = 140, M = 400. in all cases q=1.7 and L $^{(2)}$ (). The thick line { universal function F $^{(2)}$ (C).

perform the straightforward calculations (involving the entire array) and compare their results to those, obtained on truncated C_q -networks. The results of this comparison, shown in Fig.4, demonstrate a very good accuracy already at moderate values of q=1:7. This accuracy is reached at the network, which includes only about a half of all conductances of the array. Note, that although the condition q, required for general distributions P(h), is obviously not satis ed in this particular simulation, for the rectangular shape of P(h), used here, the strong inequality can be substituted by a milder condition $q < \frac{1}{3}$.

For a sam ple 140 140 w ith = 8:66 (the same realization, as used in Figs.1,2) we perform ed the calculations with dierent values of q. The results, shown in Fig.5 demonstrate fast convergence of the procedure: the difference between $F_q^{(2)}$ for q=1:7 and q=1:9 is already very small, so that using q=1:7 procedure for evaluating the universal function $F_q^{(2)}$ is a very good approximation.

From general arguments it is clear that to get self-averaging results, one should use arrays with size L > $^{(2)}$. In Fig.6 we have plotted functions F $^{(2)}$ (C), found for arrays with the same = 8:66, but with dierent sizes L. For these arrays one expects $^{(2)}$ C P $(h_{\! \rm c})$] 2 = C $3\!\!\!$ 0 3 = 93C (with unknown numerical coecient C). We see that for L > 100 the curves become almost identical, so we conclude that C 0.5 1 and square arrays with L > P $(h_{\! \rm c})$] 2 can empirically be considered as

FIG. 4: Com parison of the solutions of the full set of equation for the 40-40 sample with =1.734 (solid line) and the set, truncated according to the q-procedure with q=1.7 (broken line).

FIG. 5: Comparison of the solutions, using q-procedure with dierent q. One can see that the dierence between q=1:7 and q=1:9 results is already negligible.

large enough.

FIG. 6: Comparison of solutions for di erent lattice sizes L. All curves are obtained for largest standard deviation = 8:66 by the q-procedure with q = 1:7, and averaged over M = 400 realizations.

error interval near the curve with = 8:66, L = 140.

C on clusions. Thus, the dependence of conductivity on $\ln T$ for strongly disordered arrays of grains is nonlinear and universal, contrary to the case of a regular array, for which this dependence is linear, with a nonuniversal slope. The sign of the curvature of this nonlinear function is such, that the e ects of strong disorder seem to improve the agreement between the theory and the experimental law (1). Unfortunately, the available experimental data is still not su cient for a direct quantitative comparison of theory and experiment. In particular, it is hard to make reliable estimates for T_R and G (T_R) . It is also worth reminding that the one-loop RG, which is the basis of the present theory, is valid at temperatures well above the metal-insulator transition.

The universality of the temperature dependence of the conductivity is the direct consequence of the universality of the critical network, which carries the current in a highly inhomogeneous system. This critical network in a granular lm appears to be electively two-dimensional, if

the lm's thickness L is less than the three-dimensional correlation length $^{(3)}$ a 3 , the latter being large at high level of disorder.

We are grateful to M.V. Feigelman, D.S. Lyubshin and M.A. Skvortsov for useful discussions. Special thanks are due to D.S. Lyubshin for his invaluable advises, concerning the numerical aspect of this work. The project was supported by the Program \Quantum Macrophysics" of RAS and by RFBR grant 06-02-16533.
