A bstract

We study the properties of superconductor in presence of a nite concentration of repulsive centers. The superconductor is described by the negative U Hubbard model while repulsive centers are treated as random by distributed impurities with repulsive interaction. A nabyzing the paring potential and local density of states at impurity sites we not a wide range of the system parameters where the — like state could possibly be realized. Comparison of our results to the single repulsive center case is also given.

K ey words: superconductivity, non-m agnetic im purities, tunneling PACS: 74.20.-z; 74.25.-q; 74.40.+k; 74.50.+r

A superconducting system is regarded as in the phase if there is a sign change of the order parameter between two subsystems. The simplest example is the junction made from two superconductors with the phase of the order param eter equal to [1,2]. In this case Josephson current becom es negative in contrast to the usual 0-phase junction. A nother example are granular high-T_c m aterials which can likely form network of microscopic -junctions 31 between small regions with di erent phases of the order param eter. In such systems the zero-energy Andreev bound states, zerobias conductance peaks, param agnetic M eisner e ect and spontaneously generated currents take place [1,2]. In our recent report [4] we have considered a single impurity with repulsive interaction embedded in a swave superconductor on two dimensional lattice showing conditions which should be ful led to obtain the ' 'state. For a uniform embedding system such a state has been found in the lim it of very strong repulsion at the impurity site. In the present paper we discuss another possibility. Our superconductor possesses a nite concentration of repulsive centers with random distribution. With such assumptions 'sates could appear for moderate values of repulsive interactions at impurities due to additional disorder in paring potential i.

The system is described by random U Hubbard model [5] with the Hamiltonian

$$H = \begin{pmatrix} X \\ t_{ij} \\ t_{ij} \end{pmatrix} c_{i}^{+} c_{j} + \frac{1}{2} \begin{pmatrix} X \\ U_{i}n_{i} & n_{i} \end{pmatrix}; \quad (1)$$

where i, j label sites on a square lattice, $t_{ij} = t$ is the hopping integral between nearest neighbor sites and is the chem ical potential. D isorder is introduced through the random site interaction U_i . Depending on site i (i = A or B with binary alloy distribution $A_{1\ c}\,B_{c}$) U_i describes attraction ($U_A < 0$) or repulsion ($U_B > 0$) between electrons with opposite spins occupying the same esite. In the Hartree-Fock approximation [6] (we dropped the Hartree terms $U_i h n_i$ i, and considered only the half eld system n=1, for simplicity) the corresponding G orkov equation at zero temperature (T=0) has the following form

 (3)

and $E_F = (T = 0)$ is the Ferm ienergy.

U sing the C oherent P otential Approximation (CPA) to treat disorder in the paring potential i [5] we have found a wide region of system parameters c, UA, UB where $^{\prime}$ $^{\prime}$ state could exist. In that cases $_{\text{A}}$ and $_{\text{B}}$ were ofdi erent sign and N $_{\text{B}}$ (E $_{\text{F}}$) θ 0.In F ig.1a and b we present the superconducting order param eter = (1 c) $_A$ + c $_B$ for attractive interaction U_A = 0:3 (Fig. 1a) and $U_B = 0.6$ and a number of U_B repulsions. We have checked that in the rst case $U_A = 0.3$ we have clear gap and N $_{\rm B}$ (E $_{\rm F}$) = 0 up to som e critical concentration of $c = c_0$, above which the system becom es norm al = 0. In the second case U $_A = 0$:6 the system s stays superconducting for any c but transits to ' state for a critical value of concentration c = q dependent on UB. Larger UB leads to smaller c1. Above this concentration N_B (E_F) \neq 0 (Fig. 1c).

For better clarity in Fig. 2a,b we have plotted local density of sates for $U_B=0.6$ and $U_A=0.3$ (Fig. 2a) and $U_A=0.6$ (Fig. 2b) Note that in both considered cases ($U_A=W=0.3$ or 0.6) the impurity bands are sym metrically located with respect to the Fermi energy as it is in case of a single repulsive in purity [4].

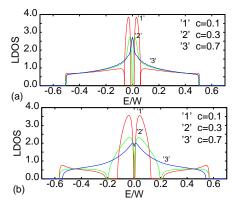

Fig. 2. Local density of states (LDOS) at the B site for $U_B=W=0:6$ and $U_A=W=0:3$ (a) or $U_A=W=0:6$ (b).

Our results in Fig. 2a show transition from superconducting system c = 0:1 and c = 0:3 with a clear gap to normal state c = 0.7. This con must be results with a single in purity [4] where it has been shown that for a relatively sm allbulk interaction the ' 'state is absent. On the other hand Fig. 2b shows the evolution of system with a clear gap around E_F (up to c = 0:3) where N_B (E) $\stackrel{\leftarrow}{\bullet}$ 0 for any E but not E = E_F (N_B (E_F) = 0). Finally for c = 0:7 N $_{\rm B}$ (E $_{\rm F}$) $\stackrel{\mbox{\scriptsize 6}}{\mbox{\scriptsize 0}}$ which could possibly correspond to a state with -like properties. A ccount for relatively large values of the random potential Uim ake Hartee-Fock approximation questionable so the results obtained here should be treated as qualitative. The presence of Hartree term s Uihni i could also change the results in some range of im purity concentration c forcing the transition to norm al state for a large enough interaction U_A [5].

In sum mary we have studied properties of the superconductor with repulsive centers and showed that for a large concentration of those centers and a large on-center Coulomb interaction system could possibly evolve to the state. Two necessary conditions for existence of the state, namely, the sign change of the pairing amplitude and non-zero the density of states at the Fermi level are fulled.
