(Dated: March 23, 2024)

A family of models is proposed to describe the motion of holes in a fluctuating quantum dimer background on the square lattice. Following Castelnovo et al. [Ann. Phys. (NY) 318, 316 (2005)], a generalized Rokhsar-Kivelson Hamiltonian at finite doping which can be mapped on a doped interacting classical dimer model is constructed. A simple physical extension of this model is also considered. Using numerical computations and simple considerations based on the above exact mapping, we determine the phase diagram of the model showing a number of quantum phases typical of a doped Mott insulator. The two-hole correlation function generically exhibits short-range or long-range algebraic correlations in the solid (columnar) and liquid (critical) phases of the model, respectively. Evidence for an extended region of a doped VBS phase exhibiting holon pairing but no phase separation is given. In contrast, we show that hole deconfinement occurs in the staggered dimer phase.

PACS numbers: 75.10.-b, 75.10.Jm, 75.40.Mg

Soon after the discovery of cuprate superconductors with high critical temperatures, Anderson suggested that the Resonating Valence Bond (RVB) state is the relevant insulating parent state that becomes superconducting under (arbitrary small) hole doping [1]. Such a state can alternatively be viewed as a spin liquid (SL), as it has no magnetic order and it does not break any lattice symmetry. Since then, the search for exotic SL in microscopic or effective models has been very active.

In quantum spin models, where magnetic frustration suppresses long-range magnetic order, spin liquids often compete with quantum disordered states named "Valence bond solids" (VBS) which break translation symmetry [2]. This is e.g. the case in the frustrated Heisenberg model with extended-range antiferromagnetic (AF) interactions [3]. In a VBS, nearest-neighbor spins pair up in bond singlets which order e.g. along columns or in a staggered arrangement. Hole doping has also been extensively studied in Mott insulators [4] and AF fluctuations have been identified as the glue for pairing. Unconventional pairing upon doping models exhibiting a VBS ground state has also been found [5].

In a pioneering work Rokhsar and Kivelson introduced a quantum dimer model (QDM), a Hamiltonian acting in the space of two-dimensional fully packed dimer configurations [6] (generically called  $\mathbb{Z}_2$ ). The dimer interaction  $V$  and the dimer-flip process  $J$  are schematically depicted in Fig. 1 (a). As discussed in Ref. 6, the QDM can be considered as the simplest effective model to describe quantum disordered phases similar to the pseudo-gap phase of the cuprate superconductors. In that respect, one might think of the dimer-flip term as originated directly from super-exchange between copper spins. At the special point  $V=J=1$ , named Rokhsar-Kivelson (RK) point, the ground state (GS) is exactly known and can be mapped onto the partition function of a classical dimer model [6].

FIG. 1: (Color online) Pictures of the two quantum processes considered in this paper. (a) Dimer flip  $J$  within a plaquette. A dimer repulsion  $V$  is defined for allippable plaquettes. (b) Hole hopping along a plaquette diagonal. In this process a dimer "rotates" from a vertical (horizontal) to a horizontal (vertical) bond. The hole-dimer repulsion  $V_{hd}$  is defined on all the dashed lines.

On the square lattice, the dimer-dimer correlations are algebraic, decaying as  $1/r^2$ . This "algebraic SL" at the RK point is believed to be rather singular on the  $V=J$  axis since, as shown e.g. by numerical calculations [7], the GS is a VBS on both sides of it, a staggered phase for  $V=J > 1$ , a columnar phase at attractive  $V$  (i.e.  $V < 0$ ), separated from the RK point by a small region of plaquette phase. The case of non-bipartite lattices, where the RK point has a gapped GS that shows fractional excita-

FIG. 2: (Color online) Mean-squared separation  $R_{hh}$  between two holes in the  $t$ - $J$ - $V$  model as a function of the ratio  $V=J$ . Calculations are done on a periodic  $6 \times 6$  cluster for two values of the hopping  $t=J$ . Inset: Size dependence of  $R_{hh}$  obtained from GPMC on  $L \times L$  clusters for  $t=J=0.5$  and two typical values of  $V=J$  showing hole-hole deconfinement and confinement, respectively.

tions [8], is also of great interest. Doping was introduced in Ref. 6 and studied further later by Syljuasen [9] who computed dimer correlations and the energy of two static monomers in a background of dimers and dynamic holes. However, hole correlations of the dynamic holes themselves, have not been investigated so far.

In this article we construct various models of doped quantum dimers with the aim to study these correlations as accurately as possible. Like the more "microscopic"  $t$ - $J$  model, the lightly doped QDM also provides a realistic description of relevant quantum disordered phases (which, in fact, would be stabilized only at finite doping in the  $t$ - $J$  model), while being much easier to handle numerically [10]. A generalized RK Hamiltonian is introduced at finite doping. This model can be mapped onto a doped interacting classical dimer model enabling an efficient use of classical Monte Carlo (MC) [11]. In addition, it offers a controllable parameter (the effective temperature) to smoothly tune the system from a VBS to a liquid phase (even at zero doping). We also extend this model to an enlarged physical space away from this so-called RK axis, where such a mapping is no longer valid [12] and where full quantum computations such as Lanczos Exact Diagonalisation (ED) and Green's function Monte Carlo (GPMC) are required. We provide evidence for hole deconfinement [13] in the algebraic dimer phase. However, we also argue that phase separation occurs for low hole kinetic energy and, lastly, provide a complete phase diagram of the model.

Let us first assume that holes are introduced by pairs on some of the dimer bonds. Next, the simplest way to account for their motion [6, 9] is to consider processes like the one depicted in Fig. 1 (b) where a hole hops along a plaquette diagonal with some amplitude  $t$ . Note that here holes are really thought of as new charge degrees of

freedom originating e.g. from doping a Mott insulator. A general form of doped QDM which operates in a Hilbert space with a fixed hole number can then be written as

$$H = \sum_c \sum_{\langle ij \rangle} c_i^\dagger c_j + J \sum_{\langle ij \rangle} \sum_{\langle kl \rangle} c_i^\dagger c_j^\dagger c_l c_k + t \sum_{\langle ij \rangle} \sum_{\langle kl \rangle} c_i^\dagger c_j^\dagger c_l c_k; \quad (1)$$

where the sum over  $\langle ij \rangle$  includes all configurations with arbitrary hole positions. The sum over  $\langle ij \rangle$  and  $\langle kl \rangle$  extends on all pairs of doped dimer coverings (only) differing by a single plaquette flip [shown on Fig. 1 (a)]. Similarly, the sum over  $\langle ij \rangle$  and  $\langle kl \rangle$  extends to all pairs of doped dimer coverings differing (only) by a single hole hopping along a diagonal of a plaquette and a single dimer "hop" from a vertical (horizontal) bond to a horizontal (vertical) bond. Such a process between two configurations  $\langle ij \rangle$  and  $\langle kl \rangle$  is depicted in Fig. 1 (b). As shown below, the role of the diagonal energies  $c$  is crucial and various choices will be discussed. Whether mobile holes remain confined [14] or not (or whether they form bound states) is the central issue of this study.

Following Ref. 6, we first start with the simple dimer interaction introduced above, namely  $c = c^0 = VN_c$  where  $N_c$  corresponds to the number of flipable plaquettes in configuration  $\langle ij \rangle$ . The properties of two holes [15] in such a  $t$ - $J$ - $V$  model [9] are studied here by ED and GPMC [16] on finite clusters and the mean-squared hole-hole distance  $R_{hh} = \langle r^2 \rangle$  is shown in Fig. 2 as a function of the dimer repulsion  $V=J$  for fixed ratios  $t=J$ . A very abrupt variation is observed at  $V=J=1$  (especially at small  $t$ ) showing a clear confinement [14] at  $V=J < 1$ , as expected in a VBS, and a large value of the hole-hole separation for  $V=J > 1$ , which scales linearly with system size (see inset of Fig 2). In this case, the undoped system is also a VBS, but a pure staggered dimer state with no quantum fluctuations. It is therefore easy to see that the two holes can freely move away from each other in opposite directions along the same diagonal creating a string of dimers at 90° from the background at no energy cost [17]. On the contrary, in a plaquette or columnar VBS the energy cost grows linearly with the string length leading to confinement. Note that it was argued that confinement is lost for a sufficiently high fraction of holes (monomers) [9].

In order to construct more general doped QDM, we briefly re-examine the undoped case (i.e. zero doping for which the  $t$  term of Eq. (1) is irrelevant) and introduce a simple construction that extends the undoped RK point to an in finite axis. Following Castelnovo et al. [18], we define the  $J$ -Hamiltonian by introducing new diagonal energies as,

$$c = c^0 = V \sum_{\langle ij \rangle} \exp \left( \frac{1}{2} V_{cl} (N_{c^0} - N_c) g \right) \quad (2)$$

where the sum extends on the dimer covering  $\langle ij \rangle$  differing from  $\langle ij \rangle$  by a single plaquette flip [shown on

FIG. 3: Schematic picture of the parameter space of the models considered here; (a) J- model (undoped) and (b) t-J- model (doped). The RK axes (thick lines parametrized by  $\beta$ ) are defined by  $J = 1$  (undoped case) and by  $J = t = V_{hd} = 1$  (doped case). The points P and R correspond to the origins at  $\beta = 0$  on these axes.

Fig. 1(a)]. In the  $\beta \rightarrow 0$  limit, the expression of  $c_c^{\text{hp}}$  reduces to  $c_c^0$  and the significance of  $V$  becomes clear. Hereafter,  $V = 1$  sets the energy scale.  $V_{cl}$  corresponds to a classical dimer-dimer interaction. We restrict ourselves to the attractive case and use units for  $\beta$  such that  $V_{cl} = 1$ . A cartoon of the Hamiltonian manifold parametrized by  $(J; \beta)$  is shown in Fig. 3(a). For  $J = 1$  it is easy to check that the GS is simply given by  $\frac{1}{Z} c_c \exp(-\frac{1}{2} V_{cl} N_c) |j\rangle$  with energy  $E_0 = 0$ , where the normalization factor  $Z = c_c \exp(-\frac{1}{2} V_{cl} N_c)$  can be considered as a partition function of a classical interacting dimer model [19]. We have checked by ED data of a  $8 \times 8$  cluster within its fully symmetric space-group irreducible representation, that the specific heat [defined as  $\frac{1}{2} (N_c^2 - N_c^2)$ ] is very close to the MC results obtained for a very large cluster (not shown). The model displays a Kosterlitz-Thouless (KT) transition [20] at  $\beta = \beta_{KT} \approx 1.536$  between a critical phase at  $\beta < \beta_{KT}$  (with varying exponents) and a columnar dimer phase [19]. Independently from our investigation, a similar mapping was derived and the properties of this critical phase were investigated with transfer-matrix techniques [21].

To investigate the expected conformational transition [13] for holes at the KT transition, let us now generalize the construction by Castelinho et al. [18] to finite doping. We define the t-J- Hamiltonian by adding a second diagonal term to the one (2) of the J- Hamiltonian,  $c_c = c_c^{\text{hp}} + c_c^{\text{hop}}$ ,

$$c_c^{\text{hop}} = V_{hd} \sum_{c^{00}(c)} \exp\left(-\frac{1}{2} V_{cl} (N_{c^{00}} - N_c) g\right) \quad (3)$$

where the sum now extends on the doped dimer coverings  $j^{00}$  connected to  $j$  by a  $t$ -process [see again Fig. 1(b)]. Note that this new term, as the  $t$ -term of (1), scales like the hole concentration.  $V_{hd}$  is a new energy scale which naturally makes sense in the  $\beta \rightarrow 0$  limit discussed below. The term (3) is of central importance

FIG. 4: (Color online) Mean-squared separation between two holes in the t-J- model as a function of  $\beta$ . ED data obtained on a  $6 \times 6$  periodic cluster are shown for several values of the hopping  $t$  and  $J = 1$ . The dashed line denotes the location of the KT transition at  $\beta_{KT} = 1.536$ . For  $t = 0.5$  and  $t = 0.6$  the "kinks" signal the appearance of a two-hole bound state.

as for  $t = V_{hd}$  and  $J = 1$  the GS can again be written as  $\frac{1}{Z} c_c \exp(-\frac{1}{2} V_{cl} N_c) |j\rangle$ . In analogy with the undoped case, we can again define a RK axis which runs along an orthogonal direction to the three-dimensional parameter space spanned by  $J$ ,  $t$ , and  $V_{hd}$ . This RK axis is given by  $J = 1$ ,  $t = V_{hd}$  and parametrized by  $\beta$ . A cartoon picture of this set of Hamiltonians is shown in Fig. 3(b). Since the hopping term (for  $t \neq 0$ ) couples all topological symmetry sectors the GS with energy  $E_0 = 0$  becomes unique. Interestingly, the procedure followed here can be generalized to more complicated dimer or hole kinetic off-diagonal processes.

The  $\beta \rightarrow 0$  limit is of special interest. As seen above, the diagonal term (2) reduces to a dimer-dimer repulsion of magnitude  $V$  (set to 1) and the undoped RK point is recovered for  $J = 1$  (when holes are not present). Similarly, the second diagonal contribution (3) reduces to a dimer-hole interaction on a plaquette [with definition given pictorially in Fig. 1(b)] of magnitude  $V_{hd}$ . The  $\beta \rightarrow 0$  limit therefore gives rise to a large class of physical Hamiltonians parametrized by arbitrary magnitudes of  $J$ ,  $t$  and  $V_{hd}$  (measured in units of  $V = 1$ ). A complete investigation of this model is left for a future study [22] and, in the following, we restrict ourselves to  $J = V$  ( $= 1$  for convenience) so that the "distance" from the RK-axis will be controlled by the deviation of  $t$  from  $V_{hd}$ .

We first start with the case of two holes in the t-J- model. The hole-hole correlations have been computed by ED of a  $6 \times 6$  cluster for arbitrary  $t$  and, for convenience, for  $V_{hd} = 1$ . Results are shown in Fig. 4. The ED results show a rather smooth variation of  $R_{hh}$  across the transition at  $\beta_{KT}$ . However, the finite size scaling at  $t = 1$  obtained by classical MC in Fig. 5(a) shows a clear qualitative change of behavior at the KT transi-

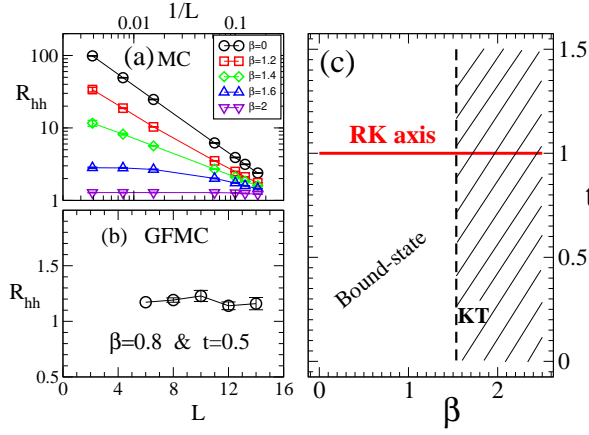

FIG. 5: (Color online) Results for 2 holes in the  $t$ - $J$ - $m$  model ( $J = V (= 1)$ ) for  $V_{hd} = V (= 1)$ . Size dependence of  $R_{hh}$  by (a) classical MC at  $t = 1$  for various values of  $\beta$  (log-log scale), (b) GPMC at  $\beta = 0.8$  and  $t = 0.5$  (linear scale). (c) Conjectured phase diagram for two holes in the thermodynamic limit for  $J = V = V_{hd} (= 1)$  vs  $\beta$  and  $t$ . The dashed region corresponds to the confined phase for  $\beta > \beta_{KT}$ .

FIG. 6: Phase diagrams of the  $t$ - $J$ - $m$  for  $V = J$  vs hole density and  $V_{hd}=t$  ratio. "PS" stands for "phase separation". (a) Phase diagram for  $\beta < \beta_{KT}$ ; (b) Phase diagram for  $\beta > \beta_{KT}$ . The boundary between the confined (doped VBS) and deconfined regions is schematic.

tion: while  $R_{hh}$  remains finite in the confined phase, it diverges as a power law in the critical phase in agreement with Ref. 19. For  $t = 0.5$  and  $t = 0.6$  we observe a kink in the ED data of Fig. 4. Moreover, for  $t = 0.25$   $R_{hh}$  remains always very close to 1, even when  $\beta \rightarrow 0$  (not shown). This signals the appearance of a two-hole bound state within the critical SL phase for  $\beta$  below  $\beta_{KT}$ . This scenario is supported by the GPMC data on larger systems shown in Fig. 5 (b). We have checked by GPMC that this bound state, in fact, persists up to  $t = 1 (= V_{hd})$ . These results are summarized in a phase diagram for two holes in Fig. 5 (c).

Lastly, using simple arguments, we construe the phase

diagram of the doped QDM for  $V = J$  (and bosonic holes). The previous finding that two holes pair up in some region of parameter space implies that either (i) a  $Q = 2e$  superconducting state or (ii) a phase separated state occurs at finite doping. For  $V_{hd} = t$ , the inverse compressibility  $\chi^{-1}$  (proportional to the second derivative of the energy per site w.r.t the hole density) identically vanishes since the GS energy vanishes on the RK axis for all number of holes. In addition, since  $V_{hd}$  acts effectively as an attraction between holes (or dimers),  $\chi^{-1}$  should be a monotonous function of the ratio  $V_{hd}=t$  as checked numerically [22]. These simple considerations imply that  $\chi^{-1} < 0$  ( $> 0$ ) for  $t < V_{hd}$  ( $t > V_{hd}$ ) and, then, the phase separation boundary is exactly given by  $t = V_{hd}$  for all hole density and  $\beta$ . Fig. 6 shows the phase diagram of the model for  $J = V$  as a function of  $t$ ,  $V_{hd}$  and hole density. For  $\beta < \beta_{KT}$ , holons are deconfined in the SL phase. We also expect a similar phase diagram for  $\beta > \beta_{KT}$  (Fig. 6(b)) although the critical line (at  $n_h = 0$ ) should be replaced by an extended (hole pair) region with VBS columnar order which survives up to a critical doping. However, the boundary of the phase separated region remains unchanged. The exact curve for the VBS/SF boundary remains to be investigated in more details.

In conclusion, we have introduced a class of simple doped QDM on the square lattice which, we believe, provide insights on the physical quantum disordered phases of real materials. An exact mapping onto a doped classical dimer model (characterized by an inverse temperature  $\beta$ ) can be realized along a one-dimensional manifold of this multi-dimensional space. Using numerical computations and simple considerations based on the above exact mapping, we determine the complete phase diagram of the model (at  $V = J$ ) showing a number of interesting physical phenomena that, we believe, could be generic in the vicinity of a Mott insulator, beyond the framework of QDM. It is found that two doped holons are confined in the columnar VBS phase. At finite doping, evidence for an extended region of a metallic VBS phase exhibiting holon pairing without phase separation is given. In contrast, we find that the algebraic dimer-dimer correlations of the (undoped) critical (quasi-ordered) phase do not provide the confinement of two injected holons. Furthermore, as shown in the case of the staggered dimer phase, we point out that holon deconfinement can even occur in a VBS.

We thank IDRIS (Orsay, France) for allocation of CPU time on the NEC-SX5 supercomputer. We are indebted to P. Pujol for many useful suggestions and thank G. Misguich for interesting discussions. D.P. also thanks S. Kivelson for useful comments. This work was partially supported by the Swiss National Fund and by M&NEP. F.B. is partially supported by COFIN 2004, COFIN 2005 (Italy), and by CNRS (France).

- [10] Fermionic spin-1/2 spinon degrees of freedom are not included in the QDM, which is justified in pseudo-spin gap phases for energies below the gap.
- [11] A.W. Sandvik and R. Moessner, preprint cond-mat/0507277.
- [12] This is important as properties of RK Hamiltonians are not believed to be generic, as they essentially realize d-dimensional classical phases.
- [13] We abusively use the term "deconfinement" for the critical liquid phase whereas strictly speaking, a marginal confinement still occurs due to the power-law hole-hole correlations (see W. Krauth and R. Moessner, *Phys. Rev. B* 67, 064503 (2003)).
- [14] By "confinement" we implicitly mean (based on qualitative arguments) that the onset of the two hole continuum is pushed up to (strictly speaking) infinite energy. This is fundamentally different from a simple two hole bound state which can appear in a liquid dimer state.
- [15] For two holes (which live on separate sublattices) quantum statistics does not play a role. At finite doping, the mapping discussed here also applies for bosonic holes (holons); for a discussion on the statistics of holons see S. Kivelson, *Phys. Rev. B* 39, 259 (1989).
