

# Carrier relaxation mechanisms in self-assembled (In,Ga)As/GaAs quantum dots: Efficient $P \rightarrow S$ Auger relaxation of electrons

Gustavo A. Narvaez, Gabriel Bester, and Alex Zunger  
National Renewable Energy Laboratory, Golden, Colorado 80401  
(Dated: November 18, 2021)

We calculate the  $P$ -shell-to- $S$ -shell decay lifetime  $\tau(P \rightarrow S)$  of electrons in lens-shaped self-assembled (In,Ga)As/GaAs dots due to Auger electron-hole scattering within an atomistic pseudopotential-based approach. We find that this relaxation mechanism leads to fast decay of  $\tau(P \rightarrow S) \sim 1 - 7$  ps for dots of different sizes. Our calculated Auger-type  $P$ -shell-to- $S$ -shell decay lifetimes  $\tau(P \rightarrow S)$  compare well with data in (In,Ga)As/GaAs dots, showing that as long as both electrons and holes are present there is no need for an alternative polaron mechanism.

## I. INTRODUCTION

Upon photoexcitation of an electron and hole in the barrier of an (In,Ga)As/GaAs self-assembled quantum dot the carriers relax to their ground states through a complicated dynamics. Much debate has taken place on the mechanisms responsible for the final stages of the non-radiative decay dynamics, which have been observed to involve relaxations of about 40-60 meV and take place surprisingly fast—within 2-60 ps. These decay times are much smaller than the radiative recombination times  $\tau_R \sim 1$  ns observed in (In,Ga)As/GaAs dots.<sup>1,2,3</sup> To explain this fast relaxation, three alternative mechanisms have been proposed and supported by model calculations: multiphonon-emission, Auger carrier-carrier scattering, and polaron decay. To provide a general perspective we first outline in this paper the general decay channels of photoexcited carriers in the GaAs-barrier of (In,Ga)As/GaAs self-assembled quantum dots (Sec. II), and then we focus on the  $P \rightarrow S$  Auger cooling due to electron-hole scattering, providing accurately calculated results. We use a realistic atomistic, pseudopotential-based approach (Sec. IV) that has been recently applied to successfully reproduce the magnitude of the radiative recombination lifetime of ground-state electrons and holes in (In,Ga)As/GaAs dots (Ref. 4) and CdSe colloidal dots (Ref. 5). Our results for inter-shell decay time  $\tau(P \rightarrow S)$  compare well with data from experiments in which photoexcited holes are present. Thus, as long as both an electron and hole are present the Auger mechanism can explain fast inter-shell relaxation without resorting to other (e.g. polaronic decay or multi-phonon emission) mechanisms.

## II. CHARACTERISTIC DYNAMICAL PROCESSES OF EXCITED ELECTRONS AND HOLES IN SELF-ASSEMBLED (IN,Ga)AS/GAAS QUANTUM DOTS

One distinguishes first between systems having a lone carrier, either electron or hole, and systems having both an electron and hole. A lone carrier can be produced by doping the dot<sup>6,7,8,9,10,11</sup> or by electrochemi-

cal injection.<sup>12</sup> Exciting a lone carrier and following its decay<sup>9,10,11</sup> is a specialized field and will be reviewed briefly in Sec. II C. More commonly we encounter relaxation of systems having both photoexcited electrons and holes. This is reviewed next. Figure 1 sketches four non-radiative relaxation processes that take place following photocreation of an electron-hole pair in an (In,Ga)As/GaAs quantum dot system. The electron is shown as a solid dot and the hole as a circle. The processes are illustrated with a dot with sparse confined electron (CB) states  $\{e_0, e_1, e_2\}$ , and with a much denser set of confined hole (VB) states  $\{h_0, h_1, \dots, h_k, \dots, h_N\}$  as is characteristic of self-assembled dots. The continuum of states of the wetting layer (dashed region) and GaAs barrier (shaded) are also shown schematically. The main observed carrier relaxation processes are the following.

### A. Barrier-to-wetting layer carrier capture

Non-resonant photoexcitation of an electron-hole pair in the barrier [Fig. 1(a)] often leads to capture by wetting-layer (WL) quasi-continua. This process consists of carrier thermalization within the GaAs barrier and subsequent capture by the WL. Barrier thermalization occurs within 1 ps.<sup>13,14</sup> Siegert *et al.* measured time-resolved photoluminescence (PL) signal from the wetting layer of InAs/GaAs dots at high excitation and found a capture time of  $\sim 2$  ps regardless of doping (Ref. 13). Similarly, in undoped dots, Sun *et al.* have found a capture time smaller than 2 ps (Ref. 15), while Yuan *et al.* observed a capture time of about 10 ps (Ref. 14).

### B. Carrier capture from the wetting layer into the dot

Following barrier-to-wetting layer carrier capture, the hole relaxes to the lowest-energy confined hole state  $h_N$  while the electron is captured from the bottom of the wetting layer to the highest-energy confined state [illustrated by  $P$ ; Fig. 1(b)]. Sosnowski *et al.*<sup>16</sup> found in time-resolved differential transmission experiments at low excitation in an (In,Ga)As/GaAs dot with two confined

FIG. 1: Sketch of different dynamical process experienced by photocreated carriers in a self-assembled (In,Ga)As/GaAs quantum dot: (a) Barrier-to-wetting layer (WL) carrier capture, (b) carrier capture from the wetting layer into the dot, (c) carrier relaxation within the dot, (d) thermal escape of carriers.

electron states that the electron capture time is 2.8 ps. On the other hand, a *combined* capture time has been derived from time-resolved photoluminescence (PL) experiments at high excitation by several groups. (These times are affected by the subsequent intra-dot carrier relaxation.) Siegert *et al.*<sup>13</sup> have found a capture time of 4.9 ps in undoped dots, and 5.4 ps and 6.1 ps in *n*-doped and *p*-doped dots, respectively.<sup>17</sup> Similarly, Yuan *et al.*<sup>14</sup> found a capture time within 5 ps, while Sun *et al.* found a capture time of less than 2 ps (Ref. 15).

### C. Relaxation of excited carriers within the dot

Following carrier capture from the wetting layer into the dot, carriers can experience different dynamical processes. These processes largely reflect the type of spacings that exist between various confined states. The (In,Ga)As/GaAs system has interesting properties in this respect. First, not only are these direct gap materials, but the competing band-structure valleys (*X*, *L*) are rather far energetically from  $\Gamma$  [unlike InP or PbSe (Ref. 18)], so these materials, specially InAs, are in fact *strongly* direct-gap systems. Second, the hole mass in InAs is much heavier than the electron mass, so confined hole states tend to be more densely spaced than electron states. Third, the electron states are arranged in *S*, *P*, *D* ... “shells” and each shell shows intra-shell level splittings, e.g.  $\mathcal{E}(P_1) \neq \mathcal{E}(P_2)$  are split by 1-6 meV, while inter-shell splittings are larger, e.g. *S*-*P* spacing is 40-60 meV (Refs. 6,7,8,9,11,19) (compared to  $\sim 300$  meV

in CdSe dots). Thus, the intra-shell splitting is of the order of (small wave vector) acoustic phonon energies, whereas inter-shell spacing is larger than (small wave vector) longitudinal optical phonon energies. Therefore, inter-shell relaxation via single-phonon emission due to electron-phonon coupling (within the Born-Oppenheimer adiabatic approximation) is expected to be ineffective—<sup>20,21</sup>the phonon-bottleneck effect—because energy cannot be conserved in the inter-shell relaxation process. Finally, hole states do not form shells, with exception of flat dots<sup>22</sup> (height of about 20 Å), and the splitting between hole states is about 1-20 meV, thus comparable to acoustic phonon frequencies. Given these general characteristics, the main electron- and hole-relaxation channels within the dot are:

(a) *Hole thermalization.* The hole relaxes to  $h_0$ , most likely via electron-acoustic-phonon emission. Such a hole relaxation has been found to occur within sub-ps times.<sup>16,23</sup> Moreover, Quochi and co-workers showed that the hole relaxation time depends strongly on temperature: 20 ps at 60 K and 0.8 ps at 300 K (Ref. 24). Note that in CdSe colloidal dots the existence of energy gaps of  $\sim 60$  meV *within* the valence-band quasi-continuum was shown experimentally<sup>25</sup> and theoretically<sup>26</sup> to slow down the hole thermalization.

(b) *Intra-shell electron relaxation* (e.g.  $P_2 \rightarrow P_1$ ; Fig. 1). The electron relaxes from  $P_2 \rightarrow P_1$  (1-6 meV splitting), or between magnetic-field split states, via acoustic phonon emission. From optical pump-probe measurements, Zibik *et al.* have recently deduced relaxation times of 15 ps and 35 ps for  $P_1$ - $P_2$  splittings of 3.7 meV and 5.5 meV (Ref. 10), respectively. A model calculation that adopts longitudinal acoustic phonon emission predicts, correspondingly, values of 8 ps and 34 ps.<sup>10</sup>

(c) *Inter-shell electron relaxation for sole carrier and for electron-hole pair* (e.g.  $P \rightarrow S$ ; Fig. 1) within the 40-60 meV separating the electronic shells. This relaxation is different if an electron-hole pair is present or just a sole electron (doped dot). As expected from the phonon bottleneck effect, inter-shell relaxation in (In,Ga)As/GaAs dots has been observed to be slow by Urayama and co-workers<sup>23</sup> (relaxation time of  $\sim 750$  ps) as well as Heitz and co-workers<sup>27</sup> (7.7 ns). In contrast, time-resolved optical measurements have clearly demonstrated that this inter-shell decay is a *fast* process whether a hole is present or not. For instance, in experiments in which both an electron and hole are present, Müller *et al.* have found decay times of 4.7 ps at 5 K and 2.8-1.5 ps (depending upon excitation power) at room-temperature in interband-pump-intraband-probe experiments (Ref. 19); Boogart *et al.* found 19 ps (low intensity) and 9 ps (high intensity) within 5 K and 77 K, but 7 ps (high intensity) at room-temperature, in time-resolved pump-probe differential reflectance spectroscopy (Ref. 28); Sosnowski *et al.* found 5 ps at 10 K in pump-probe differential transmission experiments (Ref. 16); De Giorgi *et al.* found 6.5 ps at 4 K (3.0 ps at high intensity) and 3.5 ps at room-temperature in time-resolved PL upconversion ex-

periments (Ref. 29); with the same experimental technique, applied to large ( $b = 350$  Å,  $h = 110$  Å) and small ( $b = 250$  Å,  $h = 30$  Å) dots, Boggess *et al* found, respectively, 1 ps and 7 ps below 100 K, and  $\sim 2.5$  ps at 200 K and 6 ps at 150 K (Ref. 30); while Siegert *et al.* found that at 80 K the  $D \rightarrow S$  decay time corresponds to 7 ps, 3 ps, and 2 ps for undoped, n-doped, and p-doped dots, respectively (Ref. 13). On the other hand, when a sole electron is present and no hole, the inter-shell relaxation time slows down by a factor of about 2-10. For instance, in n-doped (In,Ga)As/GaAs quantum dots the low-temperature  $P \rightarrow S$  relaxation time has been extracted from pump-probe infra-red spectroscopy and is in the range of 20-65 ps in the experiments of Zibik *et al.* (Ref. 9) and 40-70 ps in the experiments of Sauvage *et al.* (Ref. 11). In the latter, the room-temperature  $P \rightarrow S$  relaxation is 37 ps for  $\Delta(S - P) \simeq 54.5$  meV. Note that in earlier pump-probe interband absorption experiments at high excitation Sauvage *et al.* found a relaxation time of 3 ps at room temperature (Ref. 31). The situation is similar in colloidal dots such as CdSe, where the  $P \rightarrow S$  inter-shell relaxation in the absence of a hole slows down to  $\sim 10$  ps (Ref. 12), relative to  $\sim 1$  ps when an electron-hole pair is present.

Several relaxation mechanisms have been proposed as responsible for the fast inter-shell relaxation: multi-phonon emission,<sup>32</sup> Auger (carrier-carrier) scattering,<sup>33,34,35,36</sup> and polaron relaxation<sup>37,38,39,40</sup>. (We discuss the Auger and polaron models in Sec. III.)

#### D. Thermal escape of carriers from dot

Upon increasing temperature, the photoexcited electron and hole escape the confined states of the dot [Fig. 1(d)]. Thermal depopulation has been found to be significant at temperatures  $T > 100$  K.<sup>29,41,42</sup> However, Heitz and co-workers have found the onset to be 200 K.<sup>43</sup> In n-doped InAs/GaAs dots, Bras and co-workers showed that thermal depopulation becomes significant above 70 K (Ref. 6).

### III. AUGER AND POLARON MECHANISMS FOR $P \rightarrow S$ INTER-SHELL DECAY

#### A. Auger relaxation via electron-hole scattering

Figure 1(c) illustrates this process whereby the hot electron decays by scattering a low-lying photoexcited hole into deep hole states like  $h_k$ . Scattering takes place via the electron-hole Coulomb interaction, so this relaxation process does not take place in the absence of a photoexcited hole. For the mechanism to be effective it requires energy conservation: The excess energy of the electron has to be elastically transferred to the hole [as sketched in Fig. 1, where  $\mathcal{E}_1^{(e)} - \mathcal{E}_0^{(e)} = \mathcal{E}_0^{(h)} - \mathcal{E}_k^{(h)}$ ]. On the other hand, electronic level broadening due to

phonons effectively relaxes this stringent condition.<sup>16</sup> In (In,Ga)As/GaAs self-assembled quantum dots the  $\mathcal{E}_P^{(e)} - \mathcal{E}_S^{(e)} \sim 50$  meV whereas in CdSe colloidal dots  $\mathcal{E}_P^{(e)} - \mathcal{E}_S^{(e)} \sim 300$  meV. In the latter case the  $P \rightarrow S$  decay via Auger process is highly effective.<sup>44,45,46,47</sup> In fact, Hendry *et al.*<sup>48</sup> have demonstrated the validity of the electron-hole Auger mechanism for  $P \rightarrow S$  relaxation in CdSe dots by measuring directly the hole thermalization time (Sec. II C) versus the electron excess energy. Moreover, in Ref. 48 Guyot-Sionnest and co-workers have shown that in CdSe dots the  $P \rightarrow S$  relaxation of electrons is slowed down upon inducing hole trapping at the surface of the dots. This is strong evidence in favor of relaxation due to electron-hole Auger scattering. The effectiveness of the Auger mechanism for  $P \rightarrow S$  relaxation in self-assembled dots has been previously addressed within model Hamiltonians only.<sup>34,35</sup> Here it will be calculated by using a fully atomistic approach. When the hole is absent (due to its capture by a hole-quencher, or when only an electron is injected into the dot) the Auger mechanism is not possible. In CdSe colloidal dots the alternative mechanism corresponds to the coupling of the electrons in the dot with virtual phonons of the environment.<sup>12</sup> In (In,Ga)As/GaAs self-assembled dots the polaron decay has been proposed instead.<sup>37,39,40</sup>

#### B. Polaron decay for a single excited electron (no hole)

This mechanism has been invoked to explain the electron relaxation to state  $e_0$  in the *absence* of a hole. The confined electron states are assumed to be strongly coupled with the continuum of states arising from the phonon replicas of the localized states (e.g.  $S$ ,  $P$ ), thereby, forming stable polaron states. In turn, these polaron states relax when the phonon component of the polaron relaxes due to phonon anharmonicity.<sup>37</sup> Thus, assuming that the phonon component of the polaron originates from LO phonons, the phonon-bottleneck is circumvented by the emission of an LO and a TA phonon. This mechanism requires that the  $P$ - $S$  energy difference be of the order of the zone-center optical phonon energy. In colloidal dots  $\mathcal{E}(P) - \mathcal{E}(S) \sim 200$ -500 meV for electrons while  $\hbar\omega_{LO} \sim 30$  meV, so the polaron decay mechanism is not possible. On the other hand, for holes in colloidal dots  $\mathcal{E}(P) - \mathcal{E}(S) \sim 10$ -30 meV, which would make the polaron decay possible. In (In,Ga)As/GaAs self-assembled dots,  $\mathcal{E}(P) - \mathcal{E}(S) \sim 50$  meV for electrons and ranges from 5-20 meV for holes while  $\hbar\omega_{LO} \sim 30$  meV, thus making the polaron decay feasible.

In the case of the inter-shell  $P \rightarrow S$  transition in (In,Ga)As/GaAs, the polaron state has been predicted to relax within a few picoseconds,<sup>37</sup> leaving the excited electron in the  $S$  state. This model explains the observed relaxation times in the absence of a hole (Sec. II C).<sup>49</sup> Further data that has been taken as evidence of the polaron model in (In,Ga)As/GaAs dots corresponds

to the anticrossings in the energies of allowed magneto-photoluminescence transitions as the field is swept.<sup>50</sup> The magnitude of the anticrossings ( $\sim 3$  meV) present in the spectra is consistent with those predicted by the polaron model (Ref. 50). We note that in low-symmetry dots all states have the same  $a_1$ -symmetry even without phonon displacements, and therefore they would anticross in the presence of a magnetic field. Whether the reason for lowering the symmetry to  $a_1$  is phonon coupling or simply the correct atomistic dot symmetry of the non-vibrating dot remains to be determined.

#### IV. CALCULATION OF AUGER COOLING DUE TO ELECTRON-HOLE SCATTERING

We have calculated the Auger cooling lifetime of electrons in  $\text{In}_{0.6}\text{Ga}_{0.4}\text{As}/\text{GaAs}$  quantum dots within a pseudopotential-based atomistic approach<sup>51</sup> in order to establish if this mechanism leads to  $P \rightarrow S$  decay times within magnitude needed to explain low-excitation experiments in which a photoexcited hole is present.

##### A. Method of calculation

We begin by calculating the single-particle ladder  $\{e_0, e_1, e_2, \dots\}$  and  $\{h_0, h_1, h_2, \dots\}$  of electron and hole states, respectively, of the  $(\text{In,Ga})\text{As}/\text{GaAs}$  quantum dot. The wave function  $\psi_j$  and energy  $\mathcal{E}_j$  of these states are solutions of the atomistic single-particle Schrödinger equation

$$\left\{-\frac{1}{2}\nabla^2 + V_{SO} + \sum_{l,\alpha} v_\alpha(\mathbf{R} - \mathbf{R}_{l,\alpha})\right\}\psi_j = \mathcal{E}_j \psi_j. \quad (1)$$

Here, the actual potential of the solid (dot+GaAs barrier) is described by a superposition of (semiempirical) screened pseudopotentials  $v_\alpha$  for atom of type  $\alpha$  ( $\text{In,Ga,As}$ ) with position  $\mathbf{R}_{l,\alpha}$  within the dot or barrier, and a non-local pseudopotential  $V_{SO}$  that accounts for the spin-orbit interaction.<sup>52</sup> To solve Eq. (1), we expand  $\psi_j$  in a linear combination of Bloch bands  $u_{n,\mathbf{k}}^{(M)}(\mathbf{R})$  of material  $M$  ( $\text{InAs, GaAs}$ ), with wave vector  $\mathbf{k}$  and band index  $n$ , subjected to strain  $\tilde{\varepsilon}$ :<sup>53</sup>

$$\psi_j(\mathbf{R}) = \sum_M \sum_{n,\mathbf{k}} C_{n,\mathbf{k};M}^{(j)} u_{n,\mathbf{k};\varepsilon}^{(M)}(\mathbf{R}). \quad (2)$$

This expansion has a main advantage over a plane-wave expansion: The Bloch bands  $u_{n,\mathbf{k};\varepsilon}^{(M)}(\mathbf{R})$  can be intuitively chosen, which reduces the computational demand significantly.<sup>53</sup> To calculate the electron Auger cooling lifetime  $\tau(P \rightarrow S)$  due to electron-hole scattering at low temperatures, we proceed in two steps.

##### 1. Calculation of the Auger scattering rates for individual electron-hole configurations

We consider as initial electron-hole configurations  $|e_i h_j\rangle$  those corresponding to the electron in the  $P$ -shell states  $\{e_1, e_2\}$  and the hole in low-lying states  $h_j$ ; and as the final scattering states those that correspond to an electron occupying the  $S$ -shell state  $e_0$  and a hole in a deep state  $h_k$  [Fig. 1(c)], i.e.  $|e_0 h_k\rangle$ . Then, we calculate the net, characteristic Auger scattering rate of the transition  $|e_i\rangle \rightarrow |e_0\rangle$  ( $i = 1, 2$ ), with a hole in state  $h_j$ , by using Fermi's golden rule:

$$\frac{1}{\tau_{i_h}(e_i \rightarrow e_0)} = \frac{2\pi}{\hbar} \sum_k |J_{ij;0k}^{(eh)}|^2 \delta[E(i; j) - E(0; k)]. \quad (3)$$

Here,  $E(i_e; i_h)$  and  $E(0; k)$  correspond to the many-particle energy of the initial and final state, respectively, calculated at the single-configuration level of approximation.<sup>54</sup> The electron-hole Coulomb scattering matrix elements  $J_{ie i_h; 0k}^{(eh)}$  are given by

$$J_{ij;0k}^{(eh)} = \iint d\mathbf{R} d\mathbf{R}' \frac{[\psi_j^{(h)}(\mathbf{R})]^* [\psi_i^{(e)}(\mathbf{R}')]^* \psi_0^{(e)}(\mathbf{R}') \psi_k^{(h)}(\mathbf{R})}{\epsilon(\mathbf{R}, \mathbf{R}') |\mathbf{R} - \mathbf{R}'|}, \quad (4)$$

where  $\epsilon(\mathbf{R}, \mathbf{R}')$  is the microscopic dielectric function derived by Resta.<sup>55</sup> Note that in the actual computations, we introduce a phenomenological broadening  $\Gamma$  of the final states that allow us to replace  $\delta(x)$  in Eq. (3) with a Gaussian function  $(\Gamma\sqrt{2\pi})^{-1} \exp(-x^2/2\Gamma^2)$ . One should understand  $\Gamma$  as a phenomenological way to account for the phonon-induced (e.g. phonon broadening) finite lifetime  $\tau_h$  of the excited single-particle hole states:  $\Gamma \sim 2\pi\hbar/\tau_h$ . Considering that experimentally the relaxation of a hole in the wetting layer to  $h_0$  takes about 0.6ps (Ref. 16), we estimate a lower bound for  $\Gamma$  of 10 meV. The phenomenological parameter  $\Gamma$  has been used in previous calculations (Refs. 34 and 44).

Figure 2 shows the characteristic Auger relaxation lifetime  $\tau_{h_0}(e_1 \rightarrow e_0)$  calculated for two values of  $\Gamma$  in two lens-shaped  $\text{In}_{0.6}\text{Ga}_{0.4}\text{As}/\text{GaAs}$  quantum dots—D1 and D2—of size (252 Å, 35 Å). These dots differ only in the random alloy disorder realization. For a phenomenological broadening  $\Gamma = 5$  meV,  $\tau_{D1}(P \rightarrow S) \sim 20$  ps and  $\tau_{D2}(P \rightarrow S) \sim 35$  ps. The strong difference shows that  $\tau_{h_0}(e_1 \rightarrow e_0)$  depends strongly upon the energy structure of the final states. For a more plausible value of the broadening,  $\Gamma = 10$  meV,  $\tau_{h_0}(e_1 \rightarrow e_0) \sim 5$  ps for both dots.<sup>56</sup> In addition, we find that  $\tau_{h_0}(e_1 \rightarrow e_0) \simeq \tau_{h_0}(e_2 \rightarrow e_0)$ ; D2 presents a difference of 1.5 ps among these lifetimes. We also show, for a comparison,  $\tau_{h_0}(e_1 \rightarrow e_0)$  for dot D1 under a hydrostatic pressure of 2.4 GPa. Because this pressure does not change significantly the intraband energy structure of the confined states, but it primarily increases the localization of their wave functions,<sup>57</sup> the characteristic relaxation lifetime is smaller than at ambient pressure.

FIG. 2: Electronic Auger cooling characteristic lifetime  $\tau_{h_0}(e_1 \rightarrow e_0)$  calculated with two phenomenological broadenings— $\Gamma = 5$  meV and 10 meV—for dots of same size  $(b,h)=(252 \text{ Å}, 35 \text{ Å})$ . Dots D1 (open squares) and D2 (solid circles) correspond to different random alloy disorder realizations.

## 2. Solution of the rate equations describing the $P \rightarrow S$ electron relaxation

Once we have calculated the characteristic times  $\tau_{i_h}(e_{i_e} \rightarrow e_0)$ , we notice that (i) at low temperatures ( $k_B T \ll \mathcal{E}_1^{(h)} - \mathcal{E}_0^{(h)}$ ) there are two relevant initial electron-hole configurations  $|1\rangle = |e_1 h_0\rangle$  and  $|2\rangle = |e_2 h_0\rangle$  that decay to a single scattering configuration  $|s\rangle = |e_0 h_k\rangle$ . (ii) In addition, due to the  $P \rightarrow P$  intra-shell relaxation, configuration  $|2\rangle$  decays to  $|1\rangle$  with a relaxation time  $\tau(e_2 \rightarrow e_1) = \tau_{21}$  between 15 ps and 35 ps.<sup>9</sup> Thus, we find the time-dependent occupation of  $n_1$ ,  $n_2$ , and  $n_s$  by solving numerically the following set of rate equations.

$$\begin{aligned} \frac{dn_1}{dt} &= -[\gamma^{(+)} + (\tau_{h_0}(e_1 \rightarrow e_0))^{-1}]n_1 + \gamma^{(-)}n_2 \\ \frac{dn_2}{dt} &= -[\gamma^{(-)} + (\tau_{h_0}(e_2 \rightarrow e_0))^{-1}]n_2 + \gamma^{(+)}n_1 \\ \frac{dn_s}{dt} &= [\tau_{h_0}(e_1 \rightarrow e_0)]^{-1}n_1 + [\tau_{h_0}(e_2 \rightarrow e_0)]^{-1}n_2 \end{aligned} \quad (5)$$

with initial conditions taken to be  $n_1(0) = n_2(0) = 1/2$  and  $n_s(0) = 0$ . These initial conditions reflect the fact that the electrons captured in the dot have the same probability to decay to  $P_1$  or  $P_2$  (see Sec. II C).

Here,  $\gamma^{(+)}$  and  $\gamma^{(-)}$  are the rates of transitions  $n_1 \rightarrow n_2$  and  $n_2 \rightarrow n_1$ , respectively, with

FIG. 3: (Color online.) Auger cooling lifetime  $\tau(P \rightarrow S)$  vs temperature for seven lens-shaped quantum dots of different sizes. The pair  $(b,h)$  indicates the base diameter and height of the dots. Data from Refs. [13,16,19,41] are also shown.

$$\gamma^{(+)} = \frac{1}{\tau_{21}} [\exp(\Delta E/k_B T) - 1]^{-1} \quad (6)$$

and

$$\gamma^{(-)} = \frac{1}{\tau_{21}} [1 + (\exp(\Delta E/k_B T) - 1)^{-1}]; \quad (7)$$

where  $\Delta E = E(2;0) - E(1;0)$ . Finally, we extract electron Auger relaxation  $\tau(P \rightarrow S)$  by fitting the time-dependence of the occupation probability  $n_s$  to the expression  $1 - \exp[-t/\tau(P \rightarrow S)]$ . For the characteristic times  $\tau_{h_0}(e_1 \rightarrow e_0)$  and  $\tau_{h_0}(e_2 \rightarrow e_0)$  calculated with  $\Gamma = 10$  meV, and  $\tau_{21} = 15$  ps, the fit is excellent.

## B. Predicted $\tau(P \rightarrow S)$ and comparison with data

Figure 3 shows  $\tau(P \rightarrow S)$  versus temperature for lens-shaped dots of different sizes  $[(b,h)]$ . In these calculations the broadening  $\Gamma = 10$  meV is larger than the average energy spacing of the relevant final states and  $\tau_{21} = 15$  ps. Two features are prominent. (i)  $\tau(P \rightarrow S)$  decreases with both increasing height at a fixed base and increasing base at a fixed height. (ii) The Auger cooling lifetime of  $(150 \text{ Å}, 75 \text{ Å})$  is similar to that of dots with size  $(252 \text{ Å}, 35 \text{ Å})$  due to their similar single-configuration exciton gap (see below). *Comparison with data:* In Fig. 3 we also show data extracted from differential transmission spectroscopy experiments (Ref. 41) and time-resolved photoluminescence experiments (Refs.

FIG. 4: Calculated Auger-cooling lifetime  $\tau(P \rightarrow S)$  at  $T = 10$  K versus the single-configuration exciton gap for several lens-shaped quantum dots.

[13,16,19]) in (In,Ga)As/GaAs dots appear as squares and diamonds. A comparison with our calculated values shows the following. (i) We find excellent agreement between our calculated  $\tau(P \rightarrow S)$  for the (252 Å, 35 Å) dot D1 and the value of 5.2 ps found by Sosnowski and co-workers in differential transmission spectroscopy in (In,Ga)As/GaAs dots with gap of 1.265 eV (Ref. 16). Dot D2 and the dot with size (150 Å, 75 Å) also compare well with experiment. (ii) The value of 2.5 ps for  $\tau(P \rightarrow S)$  at 5 K (Fig. 3) in InAs/GaAs dots with energy gap of 1.08 eV that has been derived by Müller *et al.* (Ref. 19) from pump-probe intraband spectroscopy is in satisfactory agreement with our predicted values for (252 Å, 50 Å), (252 Å, 65 Å), and (200 Å, 75 Å) dots. (iii) Our results for the flat dot ( $h = 20$  Å and 35 Å) compare well with the  $\tau(P \rightarrow S)$  data of Norris *et al.* (Ref. 41) at low temperatures. The data of Siegert *et al.* (Ref. 13) below 100 K is comparable to our low-temperature predicted values. Note that Norris *et al.* have found that above 100 K thermal escape of carriers [Fig. 1(e)] is important, which explains the large abrupt reduction of the Auger decay time seen in the data.<sup>41</sup>

### C. Trend of $\tau(P \rightarrow S)$ with exciton gap

Figure 4(a) shows the calculated low-temperature (10 K) Auger relaxation lifetime as a function of the dot exciton gap for several  $\text{In}_{0.6}\text{Ga}_{0.4}\text{As}/\text{GaAs}$  quantum dots.<sup>58</sup> Two important features emerge: (i) We find that  $\tau(P \rightarrow S)$  ranges from 1-7 ps and decreases with the gap of the dots. As the  $S$ - $P$  splittings of the lens-shaped dots is nearly the same, we attribute the reduction of

$\tau(P \rightarrow S)$  to the *increase* of the joint density of states

$$g[E(i_e, i_h)] = \sum_k \delta[E(i_e; i_h) - E(0; k)] \quad (8)$$

that takes place as the gap of the dot *decreases*, due to the increase in the density of single-particle hole states.

### D. Comparison with other calculations for (In,Ga)As/GaAs dots

We have compared our results with two *model* calculations. (i) The 8-band  $\mathbf{k} \cdot \mathbf{p}$  calculation of Jiang and Singh (Ref. 34) and (ii) the parabolic, single-band effective-mass calculation of Ferreira and Bastard (Ref. 35). Our results agree well with the calculation in (i). Namely, Jiang and Singh show an increase of the characteristic Auger cooling lifetime with decreasing  $\Gamma$ . In addition, the results of Jiang and Singh compare satisfactorily (within a factor of two) with the value of  $\tau(P \rightarrow S)$  observed by Sosnowski *et al.*<sup>16</sup> A direct comparison with (ii) is not fully applicable since Ferreira and Bastard consider different initial states than those considered here (Sec. IV A). In particular, the starting electron-hole pair states correspond, in our language, to  $|e_1 h_1\rangle$  and  $|e_1 h_2\rangle$ . However, it is interesting to see that Ferreira and Bastard find that the Auger-cooling lifetime is within 0.1 and 6 ps. Moreover, depending on the choice of initial e-h states, this lifetime either increases as gap decreases (in contrast to our predictions; Fig. 4) or viceversa.

### E. Digression: Comparison with calculations and data for CdSe colloidal dots

Wang *et al.*<sup>44</sup> have calculated  $\tau(P \rightarrow S)$  for CdSe colloidal dots using the same methodology as in this paper—pseudopotential-based atomistic approach—finding, respectively, relaxation times of 0.6 ps and 0.2 ps for a dots with radii of 29 Å and 38 Å. These results show that in contrast to  $\text{In}_{0.6}\text{Ga}_{0.4}\text{As}/\text{GaAs}$  dots,  $\tau(P \rightarrow S)$  increases with decreasing the dot gap. Moreover, for  $\text{In}_{0.6}\text{Ga}_{0.4}\text{As}/\text{GaAs}$  dots, we predict  $\tau(P \rightarrow S)$ s that are about a factor of 10 slower. The  $\mathbf{k} \cdot \mathbf{p}$ -based calculation of Efros and co-workers<sup>59</sup> predicts Auger decay lifetimes in CdSe colloidal dots of  $\sim 2$  ps almost independently of dot size for radii between 20 Å and 40 Å. While the magnitude of  $\tau(P \rightarrow S)$ s that we find in InGaAs/GaAs is comparable to that of Efros and co-workers, the gap dependence is strikingly different. On the other hand, bleaching experiments in CdSe colloidal quantum dots show that the Auger cooling lifetime of electrons is below a picosecond and *decreases* as the exciton gap *increases*.<sup>45</sup> [Note that the calculations of Wang and co-workers<sup>7</sup> capture reproduce these experimental findings.] We predict that  $\tau(P \rightarrow S) \sim 1 - 7$  ps in (In,Ga)As/GaAs self-assembled quantum dots and shows the opposite gap de-

pendence [Fig. 4]. The gap dependence of  $\tau(P \rightarrow S)$  in both colloidal and self-assembled dots is dictated by the gap (size) dependence of (i) the joint density of states [Eq. (8)] and (ii) the magnitude of the Coulomb scattering integrals [Eq. (4)]. While in (In,Ga)As/GaAs self-assembled dots the changes with size in the joint density of states prevails, in CdSe colloidal dots the changes of the Coulomb integrals dictates the gap dependence of  $\tau(P \rightarrow S)$ .

## V. SUMMARY

We have discussed several dynamical processes that photoexcited electrons and holes undergo in (In,Ga)As/GaAs self-assembled quantum dots, and calculated the inter-shell  $P$ -to- $S$  electron decay lifetime in (In,Ga)As/GaAs self-assembled dot due to Auger electron-hole scattering. When only an electron (or only a hole) is present due to doping and this sole carrier is excited by a photon, its decay must involve a non-Auger mechanism (perhaps polaron decay). But when both an electron and hole are present we show that this Auger cooling takes place within picoseconds, which makes it an efficient inter-shell relaxation process compared to radiative recombination ( $\sim$  ns). In addition, we predict that

the lifetime  $\tau(P \rightarrow S)$  increases with the exciton gap. Our pseudopotential-based calculations confirm earlier predictions of simplified, *model* calculations. The values we find for  $\tau(P \rightarrow S)$  compare well with recent data in the presence of photoexcited holes. This finding complemented with our review of the data in the literature allows us to conclude that in the presence of a photoexcited hole there is no need to invoke the alternative polaron-decay mechanism for inter-shell electron relaxation. This conclusion could be tested in (In,Ga)As/GaAs dots by measuring the rate of hole thermalization versus the electron excess energy, or by measuring the electron relaxation rate after modifying the surface of the dot so as to cause hole trapping. Finally, a consistent picture of electron relaxation within quantum dots appears to demand two relaxation mechanisms: electron-hole Auger scattering and polaron decay.
