By means of analytical and numerical methods, we study how the residual three-dimensionality a ects dynamics of solitons in an attractive Bose-Einstein condensate loaded into a cigar-shaped trap. Based on an elective 1D G ross-P itaevskii equation that includes an additional quintic selffocusing term, generated by the tight transverse con nement, we ind a family of exact one-soliton solutions and demonstrate stability of the entire family, despite the possibility of collapse in the 1D equation with the quintic self-focusing nonlinearity. Simulating collisions between two solitons is observed. Dependence of V_c on the strength of the transverse con nement and number of atoms in the solitons is predicted by means of the perturbation theory and investigated in direct simulations. The simulations also demonstrate symmetry breaking in collisions of identical solitons with a nonzero phase di erence. This elect is qualitatively explained by means of an analytical approximation.

I. IN TRODUCTION

It is well known that a trapped atom ic Bose-E instein condensate (BEC) with attractive interactions is stable if the num ber of atom s in it is below a critical value, above which collapse occurs [1]. Beneath the collapse threshold, the BEC can form stable wave packets in a one-dimensional (ID) \cigar-shaped" trap, which is tightly con ned in two (transverse) directions, and is unbound along the longitudinal axis. In that case, the stability of bright solitons is provided by balance between the quantum pressure, alias matter wave (MW) dispersion, and mean-eld attraction. A single MW soliton [2] and trains of interacting solitons [3] have been created in the cigar-shaped optical traps. However, while the trapping geometry was nearly one-dimensional, the solitons them selves were far from being 1D objects. In particular, in Ref. [2], a stable soliton was only possible if its longitudinal size exceeded the transverse size by nom ore than 20% (note that the situation was a ected by an expulsive axial potential, unavoidable in the speci c experimental setup). Recently, it was shown that the proximity of the soliton to being a 3D object strongly a ects its properties, such as the character of its motion [4] and interactions [5, 6]. In particular, it was dem onstrated that a moving soliton immersed in a cloud of thermal atoms is subjected to a temperature-dependent friction force [4]. A collision between two solitons, which are by them selves stable, in a con ned geom etry may readily lead to collapse, if the total num ber of atom s in the soliton pair exceeds the above mentioned critical value, and the phase di erence between the solitons is (close to) zero [6]. The signi cance of the elective dimensionality of MW solitary pulses is further emphasized by the recent observation of form ation of a set of nearly-3D mutually repulsive MW solitons (with a phase shift of between them) as a result of incomplete collapse in an attractive BEC with the number of atoms several times larger than the critical value [5, 7].

In addition to being a profoundly important object of fundamental studies, MW solitary waves are also natural candidates for applications, such as high-precision atom interferom etry and quantum -information processing. Thus, a thorough understanding of deviations of their behavior from that of ideal 1D solitons is important in this respect too.

In this paper we report results of theoretical investigation of the shape of stationary MW solitons and binary collisions between them in the quasi-1D regime, with the aim to identify manifestations of nonsolitonic behavior due to the residual multi-dimensionality. The e ect of the tightly conned transverse dimensional for coss-P itaevskii equation (GPE), as per Refs. [8] and [4]. In Section II, we introduce this extended GPE, nd a family of its exact one-soliton solutions, and demonstrate stability of the entire family, despite the fact that collapse occurs in the 1D equation with the quintic self-focusing term. In Section III, we investigate soliton collisions within the fram ework of this equation. On the contrary to completely elastic collisions between solitons with zero phase di erence, ' = 0, m erge into a single pulse if their relative velocity is smaller than a critical value, $2V_c$. We indicate quintic nonlinearity, good agreement with an analytic prediction derived from the perturbation theory is found. W ith a stronger quintic term, the num erical results deviate from the perturbation theory, although not dram atically. Finally, we demonstrate dynam ical symmetry breaking between identical solitons colliding with 4 ' \leq 0 (in that case, the merger does not

occur), as a function of the relative velocity. An explanation to the latter e ect is proposed. It is based on estimation of a sym metry-breaking parameter, which is a mism atch between the amplitude center and phase center of the soliton pair with $' \in 0$ (exact de nitions are given below). Reasonably good agreement between num erical results and the analytical approximation is observed. The paper is concluded by Section IV.

II. AN EFFECTIVE ONE-DIMENSIONAL GROSS-PITAEVSKIIEQUATION AND EXACT SOLITON SOLUTIONS

A. Basic equations

W e start with the standard GPE for a condensate tightly con ned in the transverse plane, with the radial coordinate r, and uncon ned in the axial direction, x:

$$ih\frac{\theta}{\theta t} = \frac{h^2}{2m} r_2^2 + \frac{\theta^2}{\theta x^2} + \frac{1}{2}m ! r^2 + \frac{4 h^2 a}{m} j j^2 ; \qquad (1)$$

where operator r_2^2 acts in the transverse plane, ! is the frequency of the trapping potential in this plane, m is the atom ic m ass, and a < 0 is the scattering length. Transition to the quasi-1D description is possible if the change of the chem ical potential due to the m ean-eld interaction is much smaller than the level spacing in the transverse trapping potential. We brie y recapitulate the corresponding derivation, following, chie y, Ref. [4]. In the quasi-1D lim it, the factorized ansatz, (r;x;t) = (x;t) (r;x;t) [9], is used to adiabatically separate fast transverse and slow longitudinal dynamics, by neglecting derivatives of with respect to the slow variables, x and t. By substituting the ansatz into Eq. (1), two decoupled equations are obtained, within the fram ework of the tight-transverse-con nem ent approximation:

$$i\hbar\frac{\theta}{\theta t} = \frac{\hbar^2}{2m}\frac{\theta^2}{\theta^2 x} + \sim ; \qquad (2)$$

$$\sim = \frac{h^2}{2m}r_2^2 + \frac{1}{2}m!^2r^2 + \frac{4}{m}nj^2;$$
(3)

where the transverse chem ical potential, ~, has to be found from the ground-state solution of Eq. (3) as a function of the 1D density, $n(x;t) = j(x;t)^2$. Physical solutions of Eq. (3) exist only if an < 0.47 [10], otherwise transverse collapse occurs [11]. In the quasi-1D limit, corresponding to an << 0.47, the transverse wave function, , is close to the ground state of the 2D harm onic potential, and can be expanded over the set of transverse eigenm odes, $'_m(r)$: (r;x) = $'_0(r) + m C_m(x)'_m(r)$. Coe cients C m are small and can be calculated perturbatively. A coordingly, the transverse chemical potential ~ can be expanded over powers of the density by means of the perturbative theory, ~ = h! + $g_{1D} n = gn^2 + \dots$, where

$$g_{1D} = 2h!a; g_2 = 24 \ln \frac{4}{3} h!a^2;$$
 (4)

as shown in Ref. [8] (the subscript 1D implies that the corresponding coe cient appertains to the standard 1D model). Substituting the expansion for ~ in Eq. (2), one arrives at an elective equation describing the soliton dynamics in the quasi-1D limit:

$$ih\frac{\theta}{\theta t} = \frac{h^2}{2m}\frac{\theta^2}{\theta^2 x} + g_{1D}jj^2 \quad g_jj^4;$$
 (5)

which is NLSE with the cubic-quintic (CQ) nonlinearity.

O ther approaches to the derivation of the e ective 1D GPE were also proposed [12, 14]. In particular, a more complex equation with nonpolynom ial (algebraic) nonlinearity was derived, by means of the variational approach to the separation of the axial and transverse wave functions, in Ref. [12]. Expanding the nonlinearity up to the quintic term, one arrives at an equation similar to Eq. (5), but with a di erent num erical coe cient.

NLSEs with the CQ nonlinearity are well known as model equations in nonlinear optics, starting with pioneer works [16]. GPEs with the CQ nonlinearity were also used in order to take into account three-body collisions in the BEC [17]. However, in the previously considered settings, these equations were always considered with a combination of

self-focusing cubic and self-defocusing quintic term s. A drastic di erence in the present case is that the quintic term is self-focusing [as seen from Eq. (4), this conclusion does not depend on the sign of scattering length a, i.e., on the self-focusing or defocusing character of the cubic term; the same conclusion follows from the expansion of the above-mentioned nonpolynom ial NLSE derived in Ref. [12]]. The use of the GPE with the \double-self-focusing" CQ nonlinearity, which is the case here, was tacitly assumed in possible, as in this case the equation gives rise to collapse. Nevertheless, we will show below that this equation generates meaningful stable solutions. In fact, if the cubic nonlinearity is self-focusing, i.e., the scattering length is negative (the case considered throughout the present work), the presence of the collapse is a relevant qualitative feature of the e ective GPE, as collapse takes place too in the full 3D equation, from which Eq. (5) was derived (even if the strong collapse in the full 3D GPE and weak collapse in the 1D CQ equation bear essential di erences). As shown in Refs. [9, 13, 15], the collapse in the 3D equation m ay be avoided under the constraint of N $j_{a} j_{=a} < 0.627$, where N is the number of atoms in the condensate, and $a_{7} = \frac{1}{h=(m!)}$ is the harm onic-oscillator length corresponding to the transverse con nem ent.

B. Soliton solutions

Below, we use Eq. (5) in the norm alized form,

$$i\frac{\theta}{\theta t} = \frac{1}{2}\frac{\theta^2}{\theta^2 x} + g_{1D}jj \quad g_{2}jj \quad ;$$
(6)

where $g_{1D} < 0$ and $g_2 > 0$ are dimensionless interaction constants. In fact, the absolute values of both of them may be additionally scaled to be 1, but we nd it more convenient to keep these coe cients as free parameters.

A fam ily of exact soliton solutions to Eq. (6) can be found as an analytical continuation of the well-known solution of the equation with the self-defocusing quintic term [16]. The result is

$$(x;t) = 2 \frac{3}{4g_2} e^{it} \frac{p_{it}}{p_{g^2}} \frac{1}{4} \cosh 2^p \frac{1}{2} x + g^{(7)}$$

$$g = \frac{1}{2} \frac{3}{g_2} g_{1D}$$
; (8)

where is the soliton's chemical potential that m ay take any value from 0 < < 1. The squared amplitude of this soliton, i.e., the maximum atom ic density at its center, is

$$A^{2} = \frac{1}{2} \frac{r}{g_{2}} \frac{3}{g_{2}} \frac{p}{g^{2}} \frac{q}{4} \qquad g; \qquad (9)$$

and the norm of the soliton, which measures the total number of atoms, is

$$N_{sol} = \frac{z_{+1}}{1} + \frac{z_{-1}}{1} + \frac{z_{-1}}$$

The soliton's norm and squared amplitude are shown, as functions of the chemical potential, in Fig. 1.

It is worth to note a drastic di erence of this soliton family from its counterpart in the model with the self-defocusing quintic term, i.e., $g_2 < 0$: in that case, the norm takes all values, $0 < N_{sol} < 1$, while the chemical potential is limited to a nite interval, $0 < < j_{jax} = 3q_D^2 = (16 jg_2 j)$. On the contrary, for the present solution family, Eq. (10) demonstrates that the norm is limited to a nite interval,

$$0 < N_{sol} < N_{max} = \frac{r}{\frac{3}{8g_2}};$$
 (11)

while is not limited from above (as said above). In fact, $N_{m ax}$ in Eq. (11) is a collapse border of the soliton family. Further, in the usual CQ model, with $g_2 < 0$, the amplitude is limited by a nite value, $A^2 < 3g_{1D} = (4g_2)$, while the width of the soliton diverges ln (j $\frac{1}{16}$ ax j $\frac{1}{2}$)¹ at j j! j $\frac{1}{16}$ ax. In contrast to this, Eqs. (7) and (9) show that the amplitude of the present soliton family diverges, $A^2 = \frac{p}{(3-q_2)}$, at ! 1, and the width of the soliton shrinks in the same limit, as $1 = \frac{p}{10}$. This asymptotic behavior of the soliton solution clearly suggests a transition to a collapsing solution at N sol! N max, see Eq. (11).

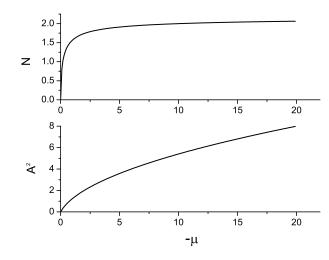

FIG.1: The upper and lower panels display, respectively, the fam ily of exact soliton solutions (7), with $g_{1D} = 1$ and $g_2 = 3=4$ [hence, g = 1, see Eq. (8)], in terms of the dependences of the norm and squared am plitude vs the chemical potential, as per Eqs. (10) and (9).

Equation (10) shows that condition dN = d < 0 holds for the entire soliton family (see also the upper panel in Fig. 1), hence the solitons satisfy the known Vakhitov-Kolokolov (VK) stability criterion [18]. As this criterion is only a necessary one, but not su cient, the stability of the solitons was tested in system atic direct simulations of Eq. (6). Results clearly suggest that all the solitons are indeed stable against sm all perturbations (of course, a large perturbation m ay provoke onset of the collapse).

It is relevant to mention that the 1D GPE with the full algebraic nonlinearity introduced in Ref. [12] gives rise to two branches of (im plicit) soliton solutions, one stable and one unstable; the branches meet and disappear at the point of transition to collapsing solutions. Equation (6) does not give rise to the second branch, as the combination of the cubic and quintic term s m ay be regarded as a truncated expansion of the full algebraic nonlinearity from the above-mentioned equation, and this truncation does not pick up the unstable branch.

It may also be relevant to note that, starting the derivation of the e ective 1D equation from the 3D GPE with the positive scattering length (corresponding to self-repulsive BEC), one will arrive at Eq. (6) with $g_{1D} > 0$ (and again with $g_2 > 0$). The corresponding equation, featuring competition between the cubic self-focusing and quintic self-defocusing terms, has a family of exact soliton solutions given by the same expressions (7)–(10), in which g is negative, as per Eq. (8). Despite the form al similarity, the latter soliton family is completely di erent from the one presented above. In particular, in the limit of ! 0 the solution is not a usual broad sm all-am plitude soliton, but rather an algebraic one,

$$=_{0} (\mathbf{x}) = \frac{3}{g_{2}} \int_{1-4}^{1-4} \frac{r}{\frac{g}{1+2g^{2}x^{2}}}$$
(12)

The most drastic di erence of the soliton family with $g_{1D} > 0$ and $g_2 > 0$ from the above one is that it features dN = d > 0, hence this entire family is unstable, according to the VK criterion [algebraic solitons, such as one in Eq. (12), are known to be unstable for a di erent reason [19]]. Besides the fact that all the solitons in the model with the positive scattering length are unstable, their physical meaning is doubtful also because the quintic term, which appears as a perturbative correction to the cubic one [8], actually dom inates over it in these solutions.

III. SOLITON COLLISIONS

A. M erger of colliding solitons with $\prime = 0$

It is commonly known that collisions between solitons in the one-dimensional NLSE, which is an integrable equation, are completely elastic. The force of interaction between the solitons depends on the relative phase between them: with 4' = 0 and ' = 0, they are attract and repeleach other, respectively [20, 21]. The quintic term breaks the integrability of the equation, and is expected to make collisions inelastic. For 4' = 0, simulations reveal a critical collision velocity, below which two identical solitons merge into a single one.

1. Analytical considerations

The merger may be explained by the fact that radiation loss due to the inelastic collision becomes greater than the initial kinetic energy of the soliton pair [21]. This explanation can be implemented in an explicit form if the quintic term is treated as a small perturbation. To this end, de ning $j_{j_{1D}}$, we rewrite Eq. (6) in the following form:

$$i\frac{\theta}{\theta t} = \frac{1}{2}\frac{\theta^2}{\theta^2 x} jj^2 jj^4;$$
(13)

where $g=g_{1D}^2$. In the zero-order approximation (= 0), the traveling-soliton solution to Eq. (13) is

$$(x;t) = A \operatorname{sech}(A(x \quad V t)) e^{-i(t \quad V x)};$$
(14)

where A and V are its am plitude and velocity, and the frequency $! = V^2 = 2 + is$ a sum of the kinetic energy and binding (potential) energy, $= A^2 = 2$, per particle.

The use of the perturbation theory makes it possible to obtain the following analytical result for the collision between solitons with equal amplitudes A, velocities V, and a phase shift 4 $'_0$ between them [21]: if the solitons are fast, $V^2 = A^2$, the energy loss generated by the emission of radiation during the collision is

$$(4 E)_{rad} = {}^{2}A^{2} A^{5} + V^{5}e V^{=A} [_{1}\cos(4') + _{2}\sin(4')];$$
(15)

where 1381, 1 2401 and 2 347. Note that the phase-dependent term s are exponentially small. In the same approximation, the collision-induced loss of the number of atom s is

$$(4 \text{ N})_{\text{rad}} = 2 = V^2 (4 \text{ E})_{\text{rad}}$$
: (16)

To estim ate a m erger condition (threshold), we assume that the velocities V, which determ ine the collision-induced losses as per Eqs. (15) and (16), are actually acquired by originally quiescent (or slow ly moving) solitons due to their mutual attraction (if 4 ' is close to zero). To this purpose, we note that the elective potential of the interaction between far separated identical solitons is, in the case of = 0,

$$U_{int}(X;4'_{0}) = 8A^{3}e^{AX}\cos(4'_{0})$$
(17)

[20], and the elective m ass of the soliton is M $_{\rm e}$ = 2A. In this approximation, the attraction accelerates the two inphase solitons to self-acquired velocities, $V_{\rm self}$, that can be found from the energy-balance equation, 2 M $_{\rm e}$ $V_{\rm self}^2$ = 8A³, hence $V_{\rm self}$ = 2A. Substituting this velocity in Eq. (15) shows that the phase-dependent part is less than 10% of the phase-independent one, and therefore we neglect it. Thus, the collision-induced loss of the energy and number of atom s (for both solitons) are predicted by the perturbation theory to be

$$(4 E)_{rad} = {}^{2}A^{7}; (4 N)_{rad} = (=2) {}^{2}A^{5};$$
(18)

where is the same num erical coe cient as in Eq. (15).

The energy of a five soliton and its norm (number of atom s), in the $= 0 \lim it$, are

$$E_{sol} = \frac{1}{3}A^3 + \frac{1}{2}M_e V^2; N_{sol} = 2A$$
 (19)

(the negative term in E_{sol} is the binding energy). First, the norm loss, 4 N, taken from Eq. (18), gives rise to the collision-induced change of the soliton's amplitude: 4 A = (4 N)_{ad}=2 = (=4)²A⁵. The corresponding change in the binding (potential) energy of both solitons is positive,

$$4 E_{bind} \quad 4 \left(\frac{2}{3}A^{3}\right) = 2A^{2}4 A = \frac{2}{2}A^{7}$$
: (20)

Finally, the energy balance predicts a change in the total kinetic energy:

$$4 E_{kin} = (4 E)_{kad} + 4 E_{bind} = (3 = 2)^2 A^7$$
: (21)

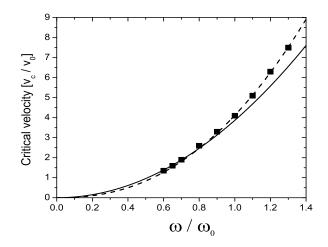

FIG.2: The critical velocity for the merger of colliding solitons, $v_c=v_0$ (as an experimentally relevant reference value, we take $v_0 = 0.21 \text{ mm/s}$, as a function of the strength of the transverse con nement, $!=!_0$ (with $!_0 = 2$ 710 Hz, as in Ref. [2]). For relatively weak con nem ent (sm aller !), dependence V_c / !² is observed, as predicted by the perturbation theory (the solid line shows the $!^2$ power law as a guide to the eye). The dashed line is the power-law to the last four points of the num erical results, yielding V_c / $!^{2:29}$ 0:07.

The merger condition states that the loss of the kinetic energy is equal to or exceeds the initial kinetic energy [21]. W ith regard to the expression for the total kinetic energy of both solitons which follows from Eq. (19), $E_{kin} = 2AV^2$, this condition means that the merger is expected if the initial velocity of each soliton falls below a critical value:

$$V^{2} < V_{c}^{2} = \frac{3}{4} {}^{2}A^{6} \frac{3}{256} {}^{2}N_{sol}^{6}$$
: (22)

The derivation of the merger threshold in plies that the critical velocity is much smaller than the above-mentioned selfacquired velocity, $V_{self} = 2A$ (then, the initial velocities of the solitons may be disregarded in the above energy-balance analysis, in comparison with V_{self} , as it was actually done). Expression (22) indeed satis es condition V_c V_{self}, as is a sm all param eter.

2. Numerical results

For simulations of soliton collisions in Eq. (6), we chose parameter values close to those in the real experiment [2], where ⁷Li atom s were used: a very small scattering length, a =0:06 nm, transverse oscillation frequency ! = 2 710 Hz, and the number of atom s $N_{sol} = 4000$. However, we did not include any external longitudinal potential, in contrast to the expulsive potential that was present in the experim ent. Recall that the expulsive potential m ade the soliton stability region very sm all [2], and actually caused the soliton to be very close to the 3D lim it. The present sinulations do not include the external potential because we are interested not in e ects produced by such a potential, but rather in sm all deviations from the one-dimensionality. In fact, a modi cation of the above-mentioned experimental setup, with the aim to make the central segment of the cigar-shaped trap free of any tangible axial potential, is quite possible.

To com pare the analytical prediction for the critical velocity, given by Eq. (22), to num erical results, it is necessary to express perturbative parameter in terms of the transverse trapping frequency !. Undoing the above renormalizations, one arrives at a conclusion that Eq. (22) in plies a quadratic dependence, V_c / $!^2$, within the framework of the perturbation theory. This dependence is indeed observed in simulations at relatively small!, as seen in Fig. (2). However, at larger !, i.e., for stronger transverse con nem ent, the num erical results feature a greater power in the V_c (!) dependence. In particular, the best t to the last four num erical points in Fig. (2) yields V_c / $!^{2:29-0:07}$, which dem onstrates a sm all but tangible deviation from the power law corresponding to the perturbation limit.

We now turn to the dependence of the critical velocity on the number of atom s, N. The analytical prediction, Eq. (22), clearly in plies V_c / N^3 . In Fig. (3), this dependence is indeed observed at smaller values of N (i.e., for weaker nonlinearity), where the perturbation lim it should naturally be valid. Perusal of num erical data shows that, in this

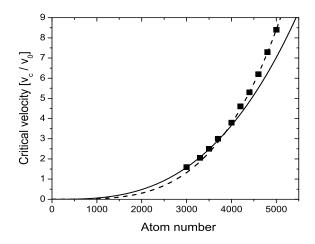

FIG.3: The critical velocity for the m erger of two solitons as a function of the number of atom s in each of the colliding solitons, N $_{sol}$. At smaller N $_{sol}$, i.e., for weaker nonlinearity, the V_c / N $_{sol}^3$ dependence is observed, as predicted by the perturbation theory, see Eq. (22). To say more accurately, the solid curve, which is the t to the rst four numerical points, features a power law V_c / N $_{sol}^{2:9}$ 0.2. The dashed curve is the power-law t to the last four points, showing a di erent power dependence, V_c / N $_{sol}^{3:62}$ 0.05.

range, the actual collision-induced radiation loss is very sm all, and, as a result, the m erger does not lead to complete fusion of the colliding solitons into a single pulse, but rather to form ation of a bound state of two solitons (\weak m erger"), as can be seen in Fig. 4. Namely, after the rst collision, the solitons re-em erge as two distinct wave packets which then collide again m any times. A similar nearly radiationless inelastic collision, leading to the form ation of a two-soliton loosely bound state, was recently observed in simulations of a weakly discrete cubic NLSE [22].

A de nite deviation from the V_c / N_{sol}^3 dependence is observed in Fig. 3 for $N_{sol} > 4000$, which shows a limitation of the perturbative predictions. In this regime of strong nonlinearity, a smooth transition in the collision process occurs, from the formation of the above-mentioned long-lived bound state to direct (\strong") merger of two solitons into a single pulse, which is accompanied by a burst of radiation. The conspicuous loss of matter with the radiation prevents the emerging single pulse from having the number of atoms above the collapse threshold, therefore the pulse does not blow up. The transition is expressed in reduction of the life time of the loss bound state before the complete merger. In Fig. 5, which represents the strongest nonlinearity included in the present fram ework, the bound state features only two oscillations.

For even stronger nonlinearities (which were also considered), the power-law dependence of V_c on the number of atom s and transverse trapping frequency is observed in the form of N $_{sol}^4$ and !³, respectively. However, in such an extrem e regime, the relevance of the quasi-1D m odel is questionable. In any case, these results convey a clear caveat to soliton experiments, in which relative variations in the atom number may be as large as ' 2: the strong power-law dependence of the critical velocity on the number of atom s should be taken into account, to avoid occasionalm erger of solitons.

B. Sym m etry breaking in soliton collisions with $\ ' \ {\mbox{\scriptsize 6}} \ 0$

We proceed to inelastic collisions of identical solitons with the phase di erence of 0 < 4' < =2. Numerical simulations of Eq. (6) show a salient e ect of symmetry breaking in this case: while the solitons separate after the collision, they emerge as two pulses with di erent am plitudes (then, the velocities are also di erent, to comply with the momentum conservation), as shown in Fig. 6. It should be mentioned that a similar e ect was observed in simulations of collisions between identical solitons in some other nonintegrable 1D models, chie y in those describing transmission of nonlinear optical pulses, within the framework of the coupled-mode theory, in waveguides equipped with B ragg gratings. In that context, the collision-induced symmetry breaking was reported in basic single-core models [23], and in more sophisticated dual-core ones [24]. A similar e ect was also observed in collisions between moving solitons in the discrete NLSE [25].

In order to achieve qualitative understanding of the symmetry breaking, we resort to consideration of an ansatz

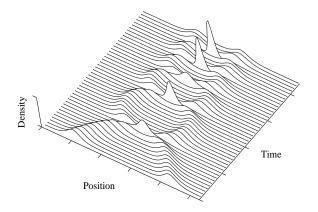

FIG. 4: Density proles as a function of time in a regime of weak merger (N sol = 3500, v=v₀ = 2). After the rst collision, the two solitons re-appear as two distinct wave pulses which then collide again many times.

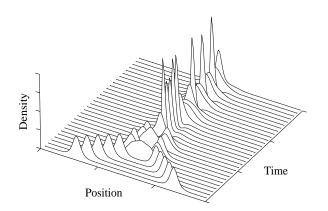

FIG. 5: The same as in Fig. 4, but in the regime of strong merger (for N_{sol} = 5000, v=v₀ = 8). A short-lived bound state quickly merges into a single breather-like pulse.

based on a form al linear superposition of two completely overlapping identical solitons (7), at some moment of time $t = t_0$, with velocities V and phases (1=2)4'. The ansatz yields the following expression:

$$ansatz (x;t) = 2e^{i(j j \frac{1}{2}V^2)t_0} t \frac{v}{p} \frac{j j}{\frac{q^2 + 4j j}{q^2 + 4j j} \cosh 2^p \frac{p}{2j j} + q} \cos(V x + 4') :$$
(23)

An essential peculiarity of this expression is that the central points of the two last multipliers do not coincide: one is found at x = 0, while the other one at x = 4' = V. This simple observation suggests a concept of the m ism atch between the amplitude center and phase center of the pair of colliding identical solitons. The m ism atch was considered as a cause of breaking the symm etry between colliding solitons in the above-m entioned m odel based on the discrete NLSE [25].

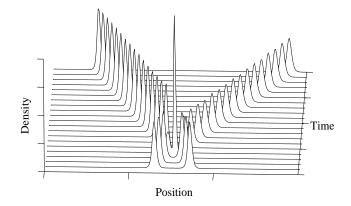

FIG. 6: Density proles of solitons featuring the symmetry breaking in the collision, for 4' = -10.

To characterize the asym m etry of ansatz (23) qualitatively, we introduce its center-ofm ass coordinate,

$$(v) \quad \frac{\frac{1}{R_{+1}} x j_{ansatz} (x) j^{2} dx}{\frac{1}{1} j_{ansatz} (x) j^{2} dx} = \frac{\sin (24')}{\frac{p}{2j j}} \frac{\cosh () \sinh () \sinh ()}{\sinh () + \cos (24') \sinh ()}$$
(24)

with V = 2j j and $\tan^1 (2^p j = g)$. For the qualitative understanding of the situation, we adopt a natural conjecture that the strongest possible symmetry breaking is attained at a value of the velocity $= \max_{\substack{m \ axp \ g}} \frac{which}{2j = g}$, and Eq. (24) simplifies:

$$(V) \quad \frac{\sin(24')}{p} \frac{\sinh(0)}{2ij} \frac{\sinh(0)}{\sinh(0)} \frac{\cosh(0)}{\cosh(0)};$$
(25)

A sym m etry parameter is shown, as a function of V, in Fig. (7) by the solid line for 4' = =10. It characterizes the degree of the collision-induced sym m etry breaking, and predicts a maximum at some nonzero velocity. Quite a similar dependence is indeed produced by num erical simulations of Eq. (6) for the same value of 4', as shown by dots in Fig. (7). The dots display values of the amplitude ratio of the output soliton pair, as found from the simulations. A ctually, the pulses emerging from the inelastic collisions are breathers with time-dependent amplitudes. Therefore, we averaged the amplitudes over long propagation distances after the collision.

G enerally, the num erical data in Fig. (7) follow the predicted sym m etry-breaking param eter. How ever, two notable deviations are observed: a nonsm ooth shape of the num erical curve (local m odulations near the m axim um, which tend to give rise to two extra local m axim a, de nitely exceed an error of the num erical simulations), and a weakly decaying tail, which im plies that the asym m etry generated by collisions between fast solitons is essentially larger than predicted by the above m odel. Note that the analytical m odel does not include radiation loss. The latter m ay enhance the asym m etry, as the loss itself is, plausibly, asym m etric too.

We note that Ref. [5], in which collisions of nearly 3D solitary waves were considered through simulations of the full 3D GPE, showed very little symmetry breaking (population transfer") between colliding solitons with the initial phase di erence of ' = =10, less than 1%. However, our results predict that the matter transfer (symmetry breaking) would be conspicuous at speci c values of the collision velocities, which m ight not be included in the analysis reported in Ref. [5]

For very sm all ', we observed chaotic behavior in the output of the collision, sim ilar to what was reported in a weakly discrete NLSE [22] (see also Ref. [26]). Very recently, chaotic behavior was predicted for collisions of more than two MW solitons, in the presence of a longitudinal parabolic trapping potential [27]. In our model, the collision between two solitons is su cient to observe chaotic behavior, which will be reported elsewhere.

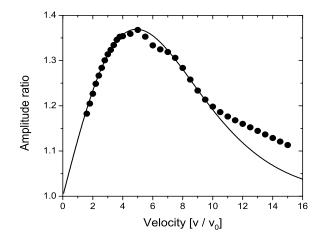

FIG. 7: Black circles show the numerically found amplitude ratio of two solitons after the symmetry-breaking collision for initial phase dierence ' = = 10. The solid line shows the velocity dependence of the symmetry-breaking parameter, as given by Eq. (25), for the same value of '.

IV. CONCLUSIONS

This work aims to understand how the tight con nem ent in transverse directions a ects the longitudinal dynam ics of matter-wave solitons in the quasi-1D setting. W ithin the framework of the known model, which reduces the multidimensional character of the full Gross-P itaevskii equation to the appendage of an additional self-focusing quintic term to the elective 1D equation, we have investigated deviations from the ideal soliton behavior.

A fam ily of exact stationary solutions for the solitons has been constructed, and it was dem onstrated that the entire fam ily is stable, despite the possibility of collapse in the modi ed 1D equation (with the negative scattering length). We have found inelastic e ects in soliton collisions, which are impossible in ideal solitons. Two identical in-phase solitons merge into a single pulse, if the collision velocity is smaller than a critical value. In fact, two dierent types of the merger were observed, \strong" and \weak" ones, the form er leading to the form ation of a bose bound state of two solitons that feature repeated collisions, with very weak radiation loss, while the latter means direct fusion into a single pulse, which is accompanied by a burst of radiation (in that case, the radiation loss helps the emerging pulse to drop the number of atom s below the collapse threshold, and thus avoid the blow up). Both the analytical approximation, based on the perturbation theory, and numerical results highlight the strong dependence of the critical velocity on the strength of the transverse con nement and the number of atoms in the solitons. Sym metry breaking in collision between identical solitons with nonzero phase di erence was also found, and partially explain by means of the calculation of a phenom enologically de ned sym metry-breaking parameter, which measures the mism atch between am plitude and phase centers of the colliding solitons.
