A bstract. We report the experimental realization of double quantum dots in singlewalled carbon nanotubes. The device consists of a nanotube with source and drain contact, and three additional top-gate electrodes in between. We show that, by energizing these top-gates, it is possible to locally gate a nanotube, to create a barrier, or to tune the chemical potential of a part of the nanotube. At low tem peratures we nd (for three di erent devices) that in certain ranges of top-gate voltages our device acts as a double quantum dot, evidenced by the typical honeycomb charge stability pattern.

1. Introduction

Since their discovery in 1991 [1] carbon nanotubes have, due to their unique mechanical and electronic properties, been subject of a trem endous scienti c and technological interest. In the eld of mesoscopic physics, carbon nanotubes o er an easily accessible experimental platform for studying the physics of the text book example of a particle trapped inside a box, a so-called quantum dot or articial atom 2, 3]. Single quantum dots can simply be realized by contacting a nanotube with two metallic contacts (norm ally made of Palladium); the contacts between the nanotube and the metallic leads usually act as tunnel barriers, characterized by the nanotube-lead tunneling rate

and a capacitance C. The energy scales for nanotube quantum dots are given by a typical single-electron charging energy $U_C = 3 \ \text{meV} = 30 \ \text{K}$ and a quantum – mechanical level spacing $E = \frac{h v_F}{2L}$, where h is Planck's constant. Using the Ferm i velocity $v_F = 8 = 10^5 \ \text{m/s}$ and an elective nanotube length $L = 1 \ \text{m}$ the level spacing amounts to $E = 2 \ \text{meV}$.

However, the standard approach for manufacturing quantum dot devices has relied on structures in G aA s-based 2-dimensional electron gases (2-D EG), which can be de ned using etching and gating techniques. The main advantage of this system is the high degree of control over the quantum dot properties, which has been achieved over the last years. These quantum dots allow for a precise tuning of the coupling to the leads by energizing locally acting gate electrodes, see e.g. [4] and references therein. A dditionally, center gates can be used in order to de ne double quantum dot structures with a tunable inter-dot coupling. This tunability is an essential ingredient for further experiments exploring the nature of electronic states in quantum dots - or, even m ore ambitious, for realizing quantum electronic devices such as spin-or charge-based quantum bits [5, 6, 7]. W hereas this high degree of control has been lacking in nanotube-based quantum dots so far, using carbon nanotubes o ers fascinating opportunities. For example, new physical phenom ena such as superconducting correlations or spin in jection into quantum dots can be studied in carbon nanotube quantum dots [8, 9]. In contrast to carbon nanotubes, up to now it has not been possible to attach ferrom agnetic and superconducting to G aA s-based quantum dots. Moreover, the in uence of the surrounding nuclear spins is expected to limit electron spin dephasing times in GaAs (double) quantum dots [10]. In carbon nanotubes, on the other hand, nuclear spins are predom inantly absent and hyper ne interactions thus strongly reduced. The question, to which degree carbon nanotube quantum dots can be tuned using locally acting gate electrodes is therefore an in portant issue to address. In this article we describe a technique of in plan enting local top-gate electrodes onto a single-walled carbon nanotube (SW NT). A fler characterizing the functionality of the top-gates we will then make use of them in order to de ne and control double quantum dots inside SW NTs.

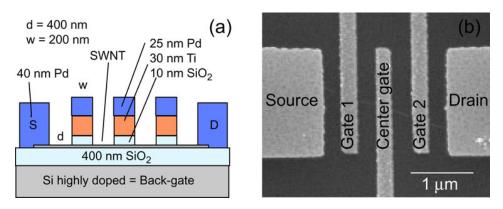

Figure 1. (a) Side-view schematic of a SW NT device with three top-gates. (b) Scanning electron micrograph of the device. Gates are labelled gate 1, center gate, and gate 2 (from source to drain).

2. Local gating of carbon nanotubes

2.1. Strategies for gating nanotube quantum dots

W ith the nanotube lying on an oxidized Si-substrate, a natural way of gating this single quantum dot is to apply a voltage to the doped Si-substrate. The Si then acts as a back-gate globally a ecting the whole quantum dot. In order to create multiple dots in such a device and control them independently, however, one will need to nd a way of locally gating a nanotube. By using such local gates, one can either create a barrier, or simply shift the chemical potential within a small part of the nanotube. In the following, we will brie y review two di erent strategies of local gating of nanotubes that have been reported in the literature, and will describe in detail the technique that has been developed in our lab. At the end of this section measurements of electrical transport through nanotube devices with local gates will be presented.

In order to fabricate gate electrodes locally acting on a nanotube, side-gates represent a straightforward option [11]. Besides source and drain contact, additional electrodes are patterned in the vicinity of the nanotube. The advantage of this technique is that contacts and side-gates can be fabricated within the same processing step. It is, however, di cult to get the side-gates as close to the nanotube as possible, yet not contacting it electrically. Thus, typically side-gates are spaced by approxim ately 100 nm from the SW NT, making the gating less e cient and their action less local.

More e cient are gates made by directly evaporating the gate electrode on top of the nanotube, with a thin gate oxide underneath. These so-called topgates are spaced from the SW NT only by the thickness of the gate oxide (1 10 nm), making them act more e ciently and (depending on their width) more locally as compared to side-gates. Despite the fact that there are draw backs of this method as well (additional processing steps, nanotube properties may be modiled underneath the top-gates), top-gates are the most promising approach for creating local barriers in SW NT. Therefore, we have developed a reliable method for fabricating top-gate electrodes in our laboratory, which

we will now discuss in more detail.

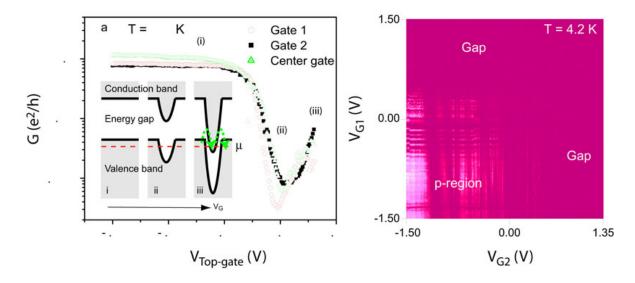

22. Experimental

SW NTs were grown on a degenerately doped Si/SiD₂ substrate by means of chem ical vapor deposition (CVD). Details of the CVD process can be found elsewhere [12]. A fter the initial preparation of SiD₂/T i/A u bond pads and alignment markers, SW NTs were then localized with a scanning electron microscope (SEM). In the following step the gate electrodes were de ned by e-beam-lithography. Electron-gun-evaporation of SiD₂ as gate-oxide, T i as gate-metal, and P d serving as anti-oxidant cover layer followed. The gate-oxide lm thickness was chosen to be 10 nm, the T i lm thickness 30 nm, and that of the P d layer 25 nm. Them aterials were evaporated at a pressure of 10⁷ m bar. In a

nal lithography and evaporation step the source and drain electrodes of the nanotube, consisting of 40 nm Pd, were de ned. The evaporation conditions were the same as described above, except the substrate was kept at a constant tem perature of 0 C by cooling the sam ple holder inside the evaporation chamber. This cooling helps to reduce outgasing ofm aterials inside the vacuum chamber due to heating during the evaporation. A fter lift-o of the remaining PMMA, the sam ples were glued into a 20-lead chip carrier and bonded. Figures 1 (a) and (b) show a side-view schematic and a scanning electron m icrograph of a typical SW NT device with three top-gates in addition to the source and drain electrode. The spacing between source and drain electrode am ounts to 22 m, and the width of the gates was chosen to be 200 nm. The back-gate oxide has a commonly used thickness of 400 nm.

2.3. E ect of local gate electrodes at 300 K and at 4.2 K

In Fig. 2(a) the linear conductance versus gate voltage of a device with three topgate electrodes is plotted. The gate-dependence identi es the sem iconducting nature of the SW NT. At a voltage of roughly 0.6 V applied to either of the three topgates the conductance through the device is suppressed indicating that the chemical potential is shifted locally into the sem iconducting gap of the SW NT. A fler a decrease of conductance for increasing gate voltage, the conductance rises again form ore positive gate voltages. This behavior is explained by the band diagram sketched in the inset of Fig. 2(a). Intrinsically the tube is p-doped and the chemical potential resides in the valence band (i). For increasing voltage at the top-gate the potential landscape is changed locally, making lie within the energy gap below the gate (ii). In this scenario the conductance through the nanotube reaches its minimum. With this technique it should thus be possible to create local barriers inside a carbon nanotube, allowing one to create arti cial potential landscapes. If the gate voltage is increased even more, the lower edge of the conduction band will eventually reach the upper edge of the valence band (iii). Now therm ally activated band-to-band processes indicated by the green arrows are possible and the conductance increases again. We have observed such behavior only at 300 K indicating the large activation barriers involved in these band-

F igure 2. (a) Linear conductance G on a logarithm ic scale for a device with three top-gate electrodes (oxide thickness 10 nm) versus top-gate-voltage at T = 300 K. The gates non swept are connected to ground potential. Inset: (i) - (iii) illustrate the band structure for increasing top-gate voltage. (b) Colorscale plot (dark=0, bright= 0.008 e²/h) of the conductance versus gate 1 and gate 2 for constant center-gate voltage at 4.2 K.

to-band charge transfer processes. B and-to-band charge transfer processes have also been reported in Ref. [13].

In Fig. 2(b) the linear di erential conductance at 4.2 K is plotted on a colorscale (bright= m ore conductive) versus voltages applied at the top-gates 1 and 2 for a constant center-gate voltage of $V_c = 1 V$. At voltages of around 0.5 V applied to either of the top-gates the chem ical potential is shifted into the energy gap of the nanotube and electrical transport is suppressed. For lower top-gate voltages, sweeping gate 1 and gate 2 leads to pronounced oscillations of the conductance due to single-electron charging and nite-size e ects of the nanotube, which are accessible at low tem peratures.

3. N anotube double quantum dots

3.1. Previous work

Recently, in the eld of double quantum dots in carbon nanotubes an enorm ous progress has been achieved. In 2004 M ason et al. rst demonstrated the local gate control of an intrinsic double quantum dot inside a carbon nanotube [15]. This work was then extended by the same group in Ref. [16], where a tunable mutual capacitance was demonstrated. In a recent work, Sapmaz et al. could observe electronic transport through excited states as seen in nite-bias triangles in a SW NT double dot [7]. In Ref. [18] m olecular eigenstates of a strongly coupled carbon nanotube double quantum dot were observed and analyzed.

3.2. Experim ental data

In this section we will show that it is possible to reliably de ne clean double quantum dots in SWNTs by using top-gate electrodes. We focus on three devices labelled A,B,C with three top-gates each. Samples A and B were fabricated according to Fig. 1(a). In the case of device C the source -drain spacing was reduced to 1.4 m and the top-gate width to 100 nm. Whereas devices A and B are based on a sem iconducting SW NT (operated in the hole regim e), device C is metallic. In Fig. 3(a)-(c) the di erential conductance versus voltages applied at two top-gates is plotted on a colorscale (bright= m ore conductive). For devices A and C the center gate has been set to a constant value of -0.1 V and 0 V, respectively, and gate 1 and gate 2 are swept. In case of device B, center gate and gate 1 are swept, while gate 2 was kept at a constant $voltage of V_{G2} =$ 0:1 V. The visible high-conductance ridges as observed for all three devices de ne a charge stability map that is shaped like a honeycom b. This honeycom b pattern is characteristic of a double quantum dot. Within each cell, the number of holes (n,m) on the two dots is constant. Energizing gate 1 (2) to more negative voltages Ils holes into dot 1 (2), whereas a more positive voltage pushes holes out successively of the dot. The fact that all three devices can be tuned to exhibit a honeycom b pattern shows that the double quantum dots are indeed de ned by the local gates and not intrinsic to the nanotube. C om m on to all three devices is that the applied gate voltages are close to 0 V, i.e. far o the pinch-o voltage. In such a regime, we expect a smooth m odulation of the electronic potential rather than sharp and steep barriers.

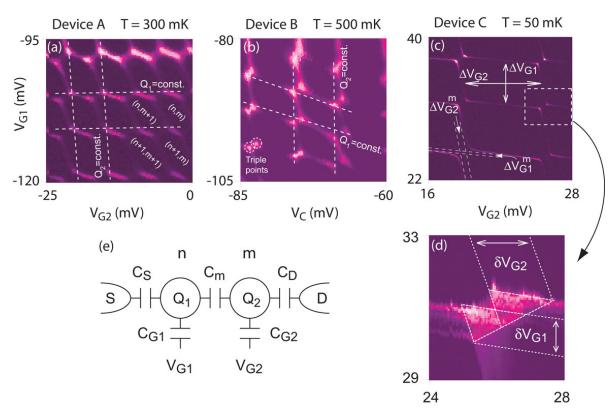

The honeycom b charge stability m ap allows for a quantitative determ ination of the double dot capacitances as de ned in the electrostatic double dot m odel in Fig.3(e), following the work of van der W iel et al. [14]. As an example we will determ ine the capacitances of the double dot de ned in device C, see Fig.3(c). From the dimensions of the honeycom b cell one can extract the gate capacitances:

$$C_{G_{1=2}} = je j = V_{G_{1=2}}$$
; (1)

yielding C_{G1} 30 aF and C_{G2} 25 aF.0 fparticular in portance are the points where three charge states are degenerate, so-called triple points. Two such points are marked by dashed circles in Fig. 3 (b) for clarity. When applying a nite bias voltage, the triple points transform into triangles, in which transport is enabled. Fig. 3 (d) shows the triple point region within the dashed box of Fig. 3 (c) at an applied source-drain voltage of $V_{sd} = 500 \text{ V}$. From the dimensions of these triangles $V_{G1(G2)}$ and

$$C_{G_{1}(G_{2})} = C_{1(2)} = jV_{sd} j = V_{G_{1}(G_{2})} ;$$
 (2)

we obtain the total capacitance $C_1 = C_s + C_{G1} + C_m$ 60 aF and $C_2 = C_d + C_{G2} + C_m$ 75 aF of dot 1 and dot 2, respectively. Here C_m denotes the mutual capacitance and $C_{s(d)}$ the capacitance of the tunnel barrier to source (drain). In a purely electrostatic model the mutual capacitance can be evaluated from the spacing of two adjacent triple points. This spacing, however, is in uenced by the tunnel coupling t in between the two dots as well. This quantum mechanical e ect leads to a level anti-crossing, resulting

F igure 3. (a) Colorscale plot of the conductance versus top-gate voltages at 300 mK for device A.B right corresponds to 0.4 e²/h. The obtained honeycom b pattern is the charge stability m ap of a double quantum dot. (b) Same for device B at 500 mK, bright corresponds to 0.08 e²/h. (c) Sam e for device C at 50 mK, bright corresponds to 0.035 e²/h. (d) Zoom into the triple point region marked by the dashed box in (c) at a bias voltage of V_{sd} = 500 V. (e) Capacitive model of a double quantum dot.

in curved wings in the vicinity of the triple points. A rough estimate of the mutual capacitance, however, can be achieved by drawing the asymptotes to the curved borders of the honeycomb, see the bottom left triple point region of Fig. 3 (c). From the vertical (horizontal) distance V_{G1}^m (V_{G2}^m) it is then possible to extract C_m by using

$$V_{G1:2}^{m} = j_{2}j_{m} = C_{G1:2}C_{2:1} :$$
(3)

We obtain a mutual capacitance of C_m 5 aF. Additionally, analyzing the curvature of the honeycom b borders allows one to precisely evaluate the tunnel coupling t. For a detailed description on this we refer to Ref. [18], where it was found that t can exceed the electrostatic nearest-neighbor interaction by asm uch as an order of m agnitude. This fact re ects the one-dimensional geometry of a nanotube; electrostatic interactions are reduced due to the large separation of the benter of mass' of the charges (while still allowing a signi cant overlap of the wavefunctions).

3.3. W here exactly are the two dots?

So far we have seen that it is possible to reliably de ne and control double quantum dots in SW NTs - the question where precisely the two dots are located, however, has not been addressed yet. As we will point out, from Fig. 3(a) and (b) it follows that the dots are separated by the center gate electrode. Recall that devices A and B are identical except that for device B the center gate (instead of gate 2) is used to control dot 2. The dashed lines in Fig. 3(a) and (b) connect triple points corresponding to a constant charge $Q_{1(2)} = \text{const}$; residing on dot 1(2). A non-zero slope of these lines indicates a cross capacitance, i.e. the gate controlling one of the two dots also a ects the chem ical potential of the other. A non-zero slope is observed for the $Q_1 = \text{const.-lines}$ in (b). Hence, the center gate a ects both dot 1 and dot 2.0 n the other hand, this is not the case for gate 1 or gate 2 in Fig. 3(a) and (b). Such behavior can be explained assuming that the two dots are separated by the center gate, screening the cross-action of gates 1 and 2. The center gate, however, located in between the dots and creating a barrier, is not screened and thus acts on the two dots. If the center gate is capable of creating a tunnel barrier inside the nanotube, so will be gate 1 and gate 2 as well. A loo recall that the voltages applied to the top-gates are all within the same range, 0 V. Consequently dot 1 is located between gate 1 and center gate, whereas V_{T op gate} dot 2 extends from the center gate to gate 2. The scenario suggested in plies that the part of the SW NT between gate 1(2) and source (drain) electrode has an e ectively energy-independent transm ission. In fact this assumption is quite reasonable, taking into account the high quality of Pd-nanotube electrical contacts [19]. Very transparent E) lead to a constant, or at least only slightly modulated transmission. contacts (Transport through our device will be dom inated by the bottleneck in transm ission - the gate-de ned double quantum dot.

4. Conclusions

In this article we have presented a reliable approach to de ne and control double quantum dots in SW NTs by using locally acting top-gate electrodes. That the double quantum dots are not intrinsic to the carbon nanotubes is con med by the presented measurements of honeycomb patterns for three dierent devices. Furthermore, using an electrostatic model, we have been able to characterize the double-dot system quantitatively by extracting its capacitances. Despite these encouraging results, further research is necessary. Challenges to master include the gate-control of the quantum - mechanical tunnel coupling of the two quantum dots and the access to regimes of only a few charge carriers per dot. Carbon nanotubes may, due to their unique properties and their experimental ease, then play an important role in future information technology.

A cknow ledgem ents

For theoretical support we are gratefully indebted to W A.Coish and D.Loss. We acknow ledge experimental contributions by J.Furer, C.Ho mann, and J.Gobrecht for oxidized Si substrates. Financial support from the Swiss NFS, the NCCR on Nanoscience, and the C.und H.D reyfus Stipendium ' (MRG) is greatly appreciated.
