#### Abstract

Social netw orks transm itting covert or sensitive inform ation cannot use all ties for this purpose. $R$ ather, they can only use a subset of ties that are strong enough to be \trusted". In this paper we consider transitivity as evidence of strong ties, requiring that each tie can only be used if the individuals on either end also share at least one other contact in com $m$ on. $W$ e exam ine the e ect of rem oving all non-transitive ties in tw o real social netw ork data sets. $W$ e observe that although som e individuals becom e disconnected, a giant connected com ponent rem ains, $w$ ith an average shortest path only slightly longer than that of the original netw ork. W e also evaluate the cost of form ing transitive ties by deriving the conditions for the em ergence and the size of the giant com ponent in a random graph com posed entirely of closed triads and the equivalent E rdos $R$ enyi random graph.

## I. INTRODUCTION

The strength of weak ties is the concept that individuals tend to be $m$ ore successfiul in acquiring inform ation about job opportunities by contacting_individuals that they did not see often | their w eak ties [-7]. The rationale behind this idea is that close friends tend to have sim ilar inform ation to us because they share sim ilar interests, profession, or geographical location. W eak ties on the other hand are betw een individuals who don't have m uch in com $m$ on, including other contacts, and the inform ation they have access to w ill tend be di erent. A shared contact betw een tw o individuals form sa closed triad (triangle), where all three people know one another. Strong ties are usually parts of triads because good friends or close professionalcontacts ofone person willtend to know one another. In this paper we $m$ ake the sim plifying assum ption that weak ties' are those that are not part of any closed triad and we de ne strong ties' are the ones that share at least one other contact in com m on. In other contexts the strength of the tie $m$ ay include $m$ easures such as frequency or length of contact, but for sim plicity here we consider only the presence of closed triads.

W hile weak ties $m$ ay be preferred in acquiring job inform ation, one $m$ ay be interested in assem bling a team or otherw ise gathering in form ation that is distributed in di erent parts of a social netw ork using only strong ties. In the case of the $M$ adrid terrorist bom bings on $M$ arch

[^0]11th, 2003, the individuals behind the attack were able to procure know ledge about $m$ aking explosive devices, hashish to trade for explosive $m$ aterials, and the explosive $m$ aterial itself using their strong ties. H ad they used weak ties which w ould have been less reliable, their plot $m$ ay have been exposed and their intentions thw arted. Sinister plots are not the only exam ple of a planning activity that can bene $t$ from using strong ties to $m$ aintain con dentiality. Scientists $m$ ay $w$ ish to forge collaborations requiring diverse expertise [ $m$ ay w ish to keep a com petitive edge by not broadcasting their ideas over weak ties. Sim ilar situations $m$ ay arise in the form ation of business alliances, where com panies seek to com plem ent their strengths through $m$ ergers, acquisitions, cross licensing of intellectual property, or joint ventures, but do not w ish to leak their next steps to com petitors.

There are also processes which describe the contagion of new ideas and practices in which the credibility of inform ation or the $w$ illingness to adopt an innovation requires independent con m ation from multiple sources. Unlike a sim ple' biological contagious agent carrying a disease, which can be transferred through a single contact between two individuals, ideas and opinions (com plex' agents) $m$ ay need to_be heard from $m$ ultiple contacts before being adopted [3]. W hether one considers teenagers deciding to buy a new brand of jeans or farm ers starting to plant a new type of com, the decisive event $m$ ay not be hearing about an innovation, but observing enough people participating to be convinced that the innovation should be adopted $\left[17_{1}, 1\right.$ 1d].

T he presence of closed triads enhances the probability that com plex contagion can spread on a netw ork. Social netw orks tend to have a m uch higher probability ofclosed
triads than the equivalent random netw orks [12, intuitive reason is given by structuralbalance theory lid which states that ties tend to be transitive: if a node is connected to two other nodes (is a member of two diads), those two nodes are much m ore likely on average to be connected than two random ly chosen nodes. Recently, it has also been show $n$ that $m$ any real world netw orks, including social netw orks, contain overlapping $k$-cliques [1] ${ }^{-1}$ ]. W ithin a $k$-clique, each of the $k$ nodes is connected to each of the otherk nodes, form ing a densely knit com m unity containing ${ }_{3}^{k}$ closed triads. Two cliques were considered overlapping if they shared $k \quad 1$ nodes, and the question was posed whether these overlapping cliques them selves form a netw ork containing a fraction of the netw ork (the netw ork percolates). In contrast, in this paper, we are interested not in the overlap of cliques, but the strength of ties betw een individuals. A m essage can be passed between two communities, even if they share only one individual in com m on, as long as that individual has strong ties $w$ ith in both com $m$ unities.

O ur results are as follow s. G iven the potential im portance of closed triads both in assem bling varied expertise and in the di usion of innovation, we rst determ ine how they are linked together in observed socialnetw orks. W e nd that rem oving non-transitive ties from these social netw orks shrinks the giant com ponent, but does not break it up. These results show that social netw orks are com posed of overlapping communities, $w$ th each com $m$ unity providing strong ties, and the overlap providing a way to traverse the netw ork using strong ties. Secondly, we seek to quantify the im pact this local structural requirem ent has on the global properties of a network, such as the phase transition in the em ergence of a giant com ponent. To this end, we m odel a random graph constructed entirely of closed triads and com pare its properties to that of an ErdosRenyi graph w ith the sam e num ber of nodes and edges. W e derive the result that the giant connected com ponent occurs at the sam e average connectivity (average degree hki=1), but that it does not grow as quickly in the triad graph as the average connectivity increases further. N um erical sim ulations reveal that the average shortest path is quite sim ilar in both netw orks. Essentially, requiring transitive closure allows fewer nodes to be connected (since $1 / 3$ of the links $m$ ust be redundant rather than reaching out to connect additionalnodes). H ow ever, the resulting connected com ponent w ill have an average shortest path that scales logarithm ically w ith the size of the graph, just as it would in an E rdosR enyigraph.

## II. SOCIALNETWORKSW ITHOUTWEAK TIES

In order to study the connectedness of social netw orks w ithout weak ties, we analyzed tw o data sets. The rst, and sm aller, data set is the social netw ork of the C lub $N$ exus online com $m$ unity at Stanford in 2001 [[1].]. M uch

| com ponent size | C lub N exus | C hub N exus <br> W ithout w eak ties |
| :--- | :--- | :--- |
| 2246 | 1 | 0 |
| 1763 | 0 | 1 |
| 6 | 0 | 1 |
| 5 | 1 | 1 |
| 4 | 1 | 2 |
| 3 | 2 | 4 |
| 2 | 8 | 0 |
| 1 | 227 | 710 |

TABLE I: D istribution of connected components in online com $m$ un ities.
like $m$ any later online social netw orking services, it allow ed individuals to sign up and list their friends on the site. T he buddy' lists w ere aggregated into a single social netw ork of reciprocated links. W ithin a few $m$ onths of its introduction, C lub N exus attracted over 2,000 undergraduates and graduates, together com prising $m$ ore than 10 percent of the total student population. The C hub N exus netw ork is only a biased subset of the com plete student social netw ork because students had free choige of how $m$ any friends to list. $N$ evertheless, the data does provide a proxy of the true social netw ork, from which one can derive interesting properties. For exam ple, triangles are quite prevalent in this netw ork, w ith a clustering coe cient of 0.17 , which is 40 tim es greater than what it would be for an equivalent E rdos $R$ enyi random graph. $T$ he average distance betw een any tw o individuals is just 4 hops.

A dam ic et al. $\left[\begin{array}{ll}{[1]} \\ \hline\end{array}\right.$ found that edges $w$ ith high betw eenness, where betw eenness re ects the num ber of shortest paths that traverse the edge, tended to connect people w ith less sim ilar pro les. These pro les included infor$m$ ation about the student's year, eld of study, personality, hobbies and other interests. The observation that ties of high betw eenness lie betw een dissim ilar individuals supports the hypothesis that weak ties bridge different com $m$ unities. Edges $w$ th high betw eenness also tend to not be part of closed triads, because each edge in the triad provides a possible altemate path. In fact, a recently-devised clustering algorithm relies on identifying com $m$ unities by rem oving edges that participate in few est closed triads and longer loops [1]. It is therefore a concem that rem oving non-transitive ties from a netw ork would tend to break it apart into disconnected com m unities. This would $m$ ean that diverse expertise $m$ ay not be reachable and new innovationsm ay not ow throughout the netw ork.

In the case of the $C$ lub $N$ exus netw ork, we can dism iss the conœem, because the netw ork is robust w ith respect to the rem oval of weak links, which account for 19\% of all links. R ather than breaking up into $m$ any disconnected com $m$ unities, the netw ork sheds som e nodes and shrinksm odestly. M ost obviously, the 239 leafnodes can-
not be part oftrianglesbecause they link to just one other node. They each becom e a disconnected com ponent w ith the rem oval of weak ties, which is justi ed in this context because they are peripheral actors. Table $\frac{1}{4}$ show s the distribution in size of the connected com ponents for the original netw ork and the network w th weak links rem oved. N ote that both netw orks have a giant com ponent containing the $m$ a jority of the nodes. The rem oval ofw eak ties does not separate com $m$ unities of large size| the largest one is com posed of just 6 nodes. The rem oval of w eak ties does cause a slight increase in the the average shortest path betw een reachable pairs. A lthough the fraction of reachable pairs drops from $72 \%$ to $51 \%$, the average shortest path increases from 3.9 hops to 4.1 .

The next netw ork we consider is the netw ork of AOL Instant M essenger ( $A \mathbb{I} M$ ) links subm itted to the website ibuddyzoo. com'. The system uses Buddy Lists to show users which buddies they have in com m on w ith their friends, to visualize their B uddy L ist, to com pute shortest paths betw een screennam es, and to show each user's prestige based on the P ageR ank [14] m easure applied to the netw ork. O ur anonym ized snapshot of the data is from 2004 and includes 140,181 users $w$ ho subm itted their buddy lists to the B uddyZoo service, as well as 7,518,816 users w ho did not explicitly register w ith BuddyZoo but were found on the registered users' Buddy Lists. This is therefore a rather large social netw ork. It w as previously studied to determ ine w hether direct links can be concealed in the netw ork, for exam ple to $m$ anipulate an online reputation $m$ echanism $\left.\overline{[ }_{1}\right]$. In the context on BuddyZoo, this would $m$ ean that two people would rem ove each other from their Buddy Lists in an attem pt to hide their connection. But unless they share no other buddies' in com $m$ on, they would stillbe linked as 'friends of friends' and arguably would have a m ore di cult tim e denying acquaintance. 9\% of the users have only a single connection, and would disconnect them selves from the netw ork if they were to rem ove it. Ofthe rem aining pairs of users, only 19\% could rem ove their direct link and be at least distance 3 from each other, while all othens would rem ain friends of friends. This is equivalent to asking what percentage of the edges are parts of triangles, which is the question we are currently interested in.

In order to determ ine the presence of strong ties, we consider only users who explicitly registered w ith BuddyZoo, but we allow an edge to be considered transitive if it is part of a closed triad that inchudes an unregistered user. This is because we know that two people share a contact, even ifthat contact did not register. W e exclude shared contacts that have indegree greater than 1000, because those could be A IM bots (autom ated response program s). We do not include unregistered contacts in the netw ork itself because their B uddy List inform ation is incom plete. The degree distribution is highly skew ed and there are $m$ any isolates in the netw ork. On average, each user is connected via a reciprocated tie to 6.83 other registered BuddyZoo users. W e require a tie to be

FIG.1: The distribution of the strength of ties, m easured as the num ber of triads each tie participates in.

FIG.2: The largest com ponent of the reduction of the B uddyZoo netw ork where each tie participates in at least 47 triads. T he triads them selves are not all shown $\mid$ only the ties that share a threshold num ber of them .
reciprocated, since it is possible for one A $\mathbb{I M}$ user to add som eone to their buddy list w ithout that person adding them in tum.

As in the case of the $C$ lub $N$ exus social netw ork, we nd that rem oving weak ties does not have a dram atic e ect on the BuddyZoo netw ork. A lthough several com $m$ unities containing a couple of dozen nodes do split o , the giant com ponent shrinks m odestly, from occupying $88.9 \%$ of the graph to occupying $87.5 \%$ of it. The average shortest path increases by a fraction of a hop from 7.1 to 7.3. U sually any lengthening in the path decreases the probability of a successfultransm ission if the probabillity that the $m$ essage is transferred at each step is less than 1 [1] [1]. H ow ever, we do not observe considerable lengthening of the average shortest path until we im pose a higher threshold on tie strength. In order to consider

TA BLE II:D istribution of connected com ponents in the BuddyZoo AOL instant m essenger com munity. A tie is considered weak if two users who list each other on their buddy lists do not list a third person in com $m$ on.

F IG. 3: The size of the giant com ponent as only ties of a $m$ inim um strength ( $m$ easured in the num ber of triads it is a part of) are kept in the netw ork. The inset show s the grow th of the average shortest path betw een connected pairs.
$m$ ore restrictive requirem ents on tie strength, we vary the strength threshold as follow s: rather considering any tie in a single closed triad to be strong, we require that it be part of at least j closed triads. Figure $1_{1}^{\prime 1}$ show s the distribution oftie strengths, where the m ean num ber of shared ties is 17.4 and the median is 13 . Figure shows the largest com ponent of nodes where each tie participates in at least 47 triads. There are several dense cliques, but the largest com ponent is quite sm all-only 233 nodes. To
investigate how rapidly the giant com ponent shrinks and how $m$ uch the average shortest distance changes, we consider reduced netw orks w here only ties of above threshold strength, $m$ easured by the num ber of triads the tie participates in, are kept. Figure ${ }_{1}$, show $s$ the giant com ponent size and average shortest path betw een allconnected pairs as the threshold is increased from zero to 35 triads. W e observe that the giant com ponent shrinks gradually, indicating that a substantial portion of the netw ork is spanned by ties of $m$ oderate strength. This would indicate that the netw ork is com posed ofoverlapping com mu nities rather than separate com $m$ unities that are bridged by w eak ties. W hat is m ore, rem oving w eak ties does not separate large com $m$ unities from one another. $R$ ather, a few $s m$ aller com $m$ unities and $m$ any isolates are spun - as the tie strength threshold is increased. Rem oving weak ties has an additional cost beyond isolating som e individualnodes and sm aller com $m$ unities | it increases the average shortest path between reachable pairs. So even though the giant com ponent is shrinking, we are rem oving the shortcuts that span it. T he average shortest path $m$ ore than doubles as we increase the threshold from 1 to 25.

The strong tie robustness of the C hub N exus and B uddyZoo netw orks is encouraging, especially in com parison to what one m ight expect in a $W$ atts-Strogatz (W S) type sm all w orld m odel [20 the W S m odel, the netw ork is constructed from a lattice $w$ here each node is connected to $k$ neighbors on each side. Fork > 1, thism eans that each node participates in local closed triads. In the $m$ odel, a fraction $p$ of the links are rew ired w ith one endpoint placed random ly am ong the nodes. It is the presence of these random links that gives the W S m odela shortest path that scales logarithm ically w ith the size of the graph. Such a link is unlikely to be part of triangle how ever, since the probability of any two nodes linking random ly is proportional to $1=\mathrm{N}$ in such a graph. Therefore, rem oving weak links in a W S m odel rem oves the shortcuts, leaving an average shortest path that scales linearly $w$ th the size of the graph. A ssum ing that nodes close together on the lattioe share sim ilar inform ation, one would need to $m$ ake many hops in order to nd novel inform ation. In section IIIIC 1, w e w ill show that the occurrence of strong ties in an E rdosR enyi graph is unlikely unless the average degree increases w ith the num ber of nodes in the netw ork. Therefore, rem oving all edges that are not part of a triangle will isolate $m$ ost of the nodes in random graphs where the average degree is constant or nearly constant w ith respect to the num ber of nodes.

> III. MODELOFARANDOM TRIANGLE GRAPH

G iven the results of the previous section, where we see a very high prevalence oftransitive ties and a robustness of the netw ork w ith respect to rem oval of w eak ties, we
seek to answ er the basic question of the cost of requiring all ties to be transitive. In order to do thiswe consider the very sim plest m odelofa random graph where every edge betw een tw o nodes is part of at least one closed triad, and investigate som e properties of the graph analytically. In essence, the graph is com posed entirely of triangles, and we model this kind of graph by assigning links am ong any three random ly chosen nodes in the graph. Strictly speaking, for a graph w th $j V j=N$ nodes, there are $N_{3}$ possible com binations of nodes that can form a triangle. E ach triangle form $s w$ ith probability b , so that on average we random ly choose $M=b \quad \begin{gathered}N \\ 3\end{gathered}$ triplets of nodes and link them w th three edges.

N ote that ourm ethod of constructing transitive graphs is sim ilar to a particular instance of the $N$ ew $m$ an [in] m odel for constructing highly clustered graphs. In the N ew m an clustered netw ork m odel, one takes a bipartite netw ork of individuals and groups. O ne then constructs a onem ode projection of the random graph by adding, $w$ ith a given probability p, edges directly betw een individuals who belong to the sam e group. H ow ever, un like [ $\left.11_{1}^{\prime} 1\right]$, in our $m$ odel the probability for nodes to connect to each other in the sam e group is 1 , and the num ber of mem bers in each group is constant at 3 .

## A. D egree distribution

W e consider the degree distribution of the graph starting from the distribution of a node belonging to k closed triads.

For each node $u$, there is a totalofR $={ }^{N}{ }_{2}{ }^{1}$ possible triangles which have $u$ as one of the vertioes. A nd, for each triple of vertices, the probability of being selected to have links in the graph is b. Let $r_{m}$ be the probability for a node belong to $m$ chosen triples. Then

$$
r_{m}=\begin{gather*}
R  \tag{1}\\
m
\end{gather*} b^{m}(1 \quad b)^{R} \quad:
$$

O n the other hand, we will now show that it is unlikely that our xed node $u$ is part oftw o trianglesw ith an edge in com $m$ on. O urnode $u$ has degree $k$ if, for som em, node $u$ is in $m$ chosen triples on a totalofk distinct nodes aside from $u$. It is straightforw ard to show that $k=2 \quad \mathrm{~m} \quad{ }_{2}^{\mathrm{k}}$. In fact, for even $k \quad N$, $m$ ost of the probability is in the case $m=k=2$, as we now show. For even $k$, the probability that $u$ has degree $k$ is the probability that $u$ is in exactly $\mathrm{k}=2$ chosen triples, adjusted for collisions of edges. C ollisions a ect the probability of degree $k$ in two ways|umay be in exactly $m=k=2$ triplesbut a collision reduces the contribution to the probability of degree $k$, or $u \mathrm{~m}$ ay be in $\mathrm{m}>\mathrm{k}=2$ chosen triples but collisions increase the contribution to the probability that the degree is k .
$C$ onditioned on $u$ falling in exactly $m$ chosen triples, all sets of $m$ triples are equally likely. There are $\underset{m}{R}=$ $\frac{N^{2 m}}{2^{m} \mathrm{~m}}$ ! possible sets of $m$ triples. $N$ ext, we want to
count the num ber of sets ofm triples involving exactly $j$ neighbors of $u$, for $j 2 \mathrm{~m}$. We can pick the $j$ neighbors as a set in ${ }^{N}{ }^{1}$ ways, but then we need to assign roles to the $j$ neighbors based on collision $m$ ultiplicity. For exam ple, suppose 4 triples am ong ve neighbors A;B;C;D;E of $u$ m ight be fu;A;Bg;fu;A;Cg;fu;A;D g;fu;B;Eg. W e can choose $A ; B ; C ; D ; E$ as a set; pick an elem ent for the role of A (that appears three tim es) in 5 ways; given that, pick an elem ent for the role of B in 4 ways; then E in 3 ways, and the rem aining elem ents take the interchangeable roles of C and D, for a total of 54035 ! orderings).

For us, a crude bound for the orderings of roles will su ce. There are at most $2 \mathrm{~m} j$ collisions counting $m$ ultiplicities, and so at $m$ ost $2 m \quad j$ neighbors of $u$ that can be in $m$ ore than one triple| play a non-trivial role. $T$ here are at $m$ ost $2 m \quad j$ roles. So the num ber of ways to assign non-trivial roles is at most $\left(\begin{array}{ll}2 m & j\end{array}\right)^{2 m} \quad j$. So the num ber of sets ofm triples involving exactly j neighbors of $u$ is at most ${ }^{N}{ }_{j}^{1} \quad(2 m \quad j)^{2 m} j^{j}$. Thus the ratio of these to the num ber of sets ofm disjoint triples is

$W$ e are intereseted in the case $2 \mathrm{~m} j \quad 1$. If $m$ and $j$ are constants, then we can ignore $2^{m} \mathrm{~m}!j$ !, and we get

By choosing the appropriately sm all probability b of choosing a triple, wem ay assum e that $m$ and $j$ are much sm aller than $N$. Butwe cannot necessarily assum em and j are constants; for exam ple, w em ay havem ! com parable to $N$. We now consider the case where j or m grows (slow ly) w ith N , and where N is su ciently large. If $m \quad j$, then $2 n m!\sum_{m}^{j} \quad 1$. It follow $s$ that

On the other hand, if $m>j$, then $2 m \quad j>m$, so

If $2 \mathrm{~m} \quad j=1$, this is $0(2 \mathrm{~m}=\mathrm{N}) \quad \mathrm{N}^{1+\circ} \mathrm{P}$ (1) . If $2 \mathrm{~m} \quad \mathrm{j}>1$, then, since we $m$ ay assum $e$ that $2 m \quad \mathrm{P} \dot{\mathrm{N}}$, we have

| $\begin{gathered} \mathrm{N} \quad{ }^{1} \quad(2 \mathrm{~m} \\ \hline \end{gathered}$ | $j)^{2 m \quad j}$ | 0 | (2m (2m | j) $=\mathrm{N})^{2 m}$ | j |
| :---: | :---: | :---: | :---: | :---: | :---: |
| \% |  |  |  |  |  |
|  |  | 0 | ( (2m | $j) \stackrel{p}{=} \bar{N})^{2 m}$ | j |
|  |  | 0 | ( 2 m | $\left.j)^{2}=\mathrm{N}\right)^{(2 \mathrm{~m}}$ |  |

This is O $\quad(2 \mathrm{~m} \quad j)^{2}=\mathrm{N} \quad \mathrm{N}^{1+\mathrm{O}(1)}$.
W e conclude that the e ect of collisions is sm allin any case. $T$ hus we get the probability of $u$ having degree $k$ is

$$
\mathrm{p}_{\mathrm{k}}=\begin{array}{llll}
\left(\begin{array}{lll}
\mathrm{R} & \mathrm{R}^{\frac{k}{2}} b^{\frac{k}{2}}(1 & \mathrm{b})^{\mathrm{k}} \frac{\mathrm{k}}{2}
\end{array} \mathrm{~N}^{1+o(1)}\right. & \text { if } \mathrm{k} \text { is even }  \tag{2}\\
N^{1+o(1)} ; & & \text { if } \mathrm{k} \text { is odd }
\end{array}
$$

A fter ignoring the additive am ount $\mathrm{N}^{1+\circ(1)}$, the corresponding generating function is given by

$$
G_{0}(z)={ }_{k=0}^{X^{R}} \quad \begin{aligned}
& R \\
& k
\end{aligned} b^{k}(1 \quad b)^{R}{ }^{k} z^{2 k}=\left[b z^{2}+1 \quad b\right] \quad \text { (3) }
$$

T he average degree hki is then given by:

$$
\begin{equation*}
\mathrm{hki}=\mathrm{G}_{0}^{0}(1)=\mathrm{b}(\mathbb{N} \quad 1)(\mathbb{N} \quad 2) \tag{4}
\end{equation*}
$$

A nd thus, we have the relationship betw een average degree hki and the probability of any three nodes being connected by a triangle b:

$$
\begin{equation*}
\mathrm{b}=\frac{\mathrm{hki}}{(\mathbb{N} \quad 1)(\mathbb{N} \quad 2)} \tag{5}
\end{equation*}
$$

W hen hki $=O(1), b=O \quad \frac{1}{\mathrm{~N}^{2}}$.

B . A ccidental triangles and the clustering coe cient

W e should notice that in ourm odel, the expected num ber of triangles in the netw ork is not exactly $\mathrm{b} \quad \begin{gathered}\mathrm{N} \\ 3\end{gathered}$. $T$ here is the possibility of form ing an \accidental" triangle, which can occur when the pairs of nodes $a$ and $b, b$ and $c$, and $a$ and $c$ are linked, but the triangle $a ; b ; c$ w as not am ong the b ${ }_{3}^{\mathrm{N}}$ initially chosen triangles. T he probability b0 of this occurring is the probability that no triangle was intentionally form ed betw een the $a, b$, and c: 1 btim es the probability that each of the three edges does occur in a triangle other than $a ; b ; c$.

$$
\left.\left.\mathrm{b}^{0}=\left(\begin{array}{lllll}
1 & \text { b) }[1 & (1 & \text { b } \tag{6}
\end{array}\right)^{3}\right)\right]^{3}
$$

In this way, we know that the total expected num ber of triangles in this graph is a $\begin{gathered}\mathrm{N} \\ 3\end{gathered}$, where $a=b+b^{0}$.

Thus, the ratio betw een the actual num ber of triangles in the graph and the input num ber of triangles is:

$$
=\frac{\mathrm{a}}{\mathrm{~b}}=1+\frac{\left(\begin{array}{llll}
1 & \text { b) }[1 & \left(\begin{array}{lll}
1 & \text { b) }
\end{array}\right)^{2} \tag{7}
\end{array}\right]^{3}}{\mathrm{~b}}
$$

H ow ever, $b^{0}$ is very sm all com pared with $b$, when the average degree of a node in the graph is a constant independent of the grow th of the total num ber of nodes $N$. Since we have show $n$ that $b=O\left(\frac{1}{N^{2}}\right)$, then it is not hard to see that the ratio of the probability for any three nodes to be part of an accidental triangle and the probability for them to be a triangle that is constructed by random ly choosing groups is:

$$
\frac{\mathrm{b}^{0}}{\mathrm{~b}}=\frac{\left(\begin{array}{llll}
1 & \mathrm{~b})\left[\begin{array}{lll}
1 & (1 & \text { b) }
\end{array}\right)^{3} \tag{8}
\end{array}\right]^{3}}{\mathrm{~b}}=0 \quad \frac{1}{\mathrm{~N}}
$$

Thus, we can see that when $N$ is large, and the average degree hki is independent of $N$, then the chance of form ing an accidentaltriangle is quite sm all com pared to the triangles random ly draw $n$ in constructing the $m$ odel. $F$ igure $\overline{1}_{\underline{4}}^{1}$ ' , , hki.

F IG . 4: The ratio of the num ber of accidentally form ed triangles to the num ber random ly chosen by the $m$ odel. For xed average degree and increasing number of nodes, the ratio of accidentally form ed triangles drops as $1=\mathrm{N}$.

In $F$ igure, $5_{1}^{\prime \prime}$ w w show three instances of a random ly generated graph of triangles. E ach graph has 1;000 nodes, but we form di erent num bers of triangles. Even though a giant com ponent exists for each graph, it is only once the num ber of triangles equals the num ber of nodes that we observe a few random triangles form ing. Therefore the form ation of accidentaltriangles does not have a substantiale ect on the derivations below.

The clustering coe cient $C$ is a $m$ easure of the prevalence of closed triads in a netw ork $\left[\overline{1} \overline{2}_{1}^{\prime}, \overline{2} \overline{2} 1\right]$. The expectation of the total num ber of connected triples of nodes (open and closed triads) in the graph is $\mathrm{N}_{\text {triple }}=$

(a) $\mathrm{N}=1000, \mathrm{M}=200$

(b) $\mathrm{N}=1000, \mathrm{M}=300$

(c) $\mathrm{N}=1000, \mathrm{M}=500$

F IG . 5: E xam ples of triangle graphs w ith 1000 nodes $w$ ith varying num bers of triangles M . A ccidental triangles are m arked w ith bold lines.

N $\quad{ }_{k}{ }_{2}^{k} p_{k}$, and the num ber of closed triads is $N$ b $\quad \mathrm{N}_{3}^{\mathrm{N}}$ since the num ber of accidentaltriangles is sm all. Thus the clustering coe cient is:

$$
\begin{aligned}
& C=\frac{3 \mathrm{~N}}{\mathrm{~N}_{\text {triple }}}
\end{aligned}
$$

$$
\begin{aligned}
& =O(1)
\end{aligned}
$$

W e can see that when $N$ is large, the clustering coe cient of our graph is:

$$
\begin{equation*}
C=O(1) \tag{9}
\end{equation*}
$$

which is signi cantly larger than the $O\left(\mathbb{N}^{1}\right)$ clustering coe cient in an ErdosRenyiR andom graph. Form any types of realw orld netw orks, it has been show $n$ that $C=$ O (1) [1] $]$, so it is of interest to see how rem oving weak ties in real netw orks changes the clustering coe cients.

## C. Phase transition and the giant com ponent

For the derivation of the phase transition and size of giant com ponent, we loosely follow the generating function $m$ ethods for clustered graphs in [121]. The phase transition is also known as the percolation threshold the average degree at which a nite fraction of the network is connected, form ing a giant com ponent. In P art A, we have given $r_{m}$, the probability for a node belong to m triangles. $T$ hus, averaging over all individuals and triangles, we haye the $m$ ean num ber of triangles a node belongs to: $=\mathrm{m}_{\mathrm{m}}$.

The probability ofhaving tw o edges w ith in the triangle
is 1 , and the probability of having any other num ber is 0 . Therefore, the generating function of the num ber of edges for each node w thin a triangle is

$$
\begin{equation*}
h(z)=z^{2} \tag{10}
\end{equation*}
$$

Furthem ore, for a node A in the graph, the totalnum ber of other nodes in the whole graph that it is connected to by virtue ofbelonging to triangles is generated by:

$$
\begin{equation*}
\left.G_{0}(z)=x_{m=0}^{X_{m}} r_{m}(z)\right)^{m} \tag{11}
\end{equation*}
$$

$w$ here $r_{m}$ is the probability for a node to belong to $m$ groups as we de ned before. T his is also the generating function of the distribution of the num ber of nodes one step aw ay from node A.

The generating function of the distribution of the num ber of nodes two steps aw ay from $A$ is $G_{0}\left(G_{1}(z)\right)$, where $G_{1}(z)$ is the generating function for the distribution of the num ber of neighbors of a node arrived at by follow ing an edge (excluding the edge that was used to arrive at the node) :

$$
\begin{equation*}
G_{1}(z)=1_{m=0}^{X^{1}} \operatorname{mr}_{m}(\mathrm{~h}(\mathrm{z}))^{\mathrm{m} \quad 1} \tag{12}
\end{equation*}
$$

The necessary and su cient condition for a giant com ponent to exist, is when, averaging over all the nodes in the graph, the num ber of nodes tw o steps aw ay exceeds the num ber of nodes one step aw ay [1] $]$, which can be
expressed as:

$$
\begin{equation*}
\left.\mathbb{C}_{z}\left(\mathrm{G}_{0}\left(\mathrm{G}_{1}(\mathrm{z})\right) \quad \mathrm{G}_{0}(\mathrm{z})\right)\right]_{\mathrm{z}=1}>0 \tag{13}
\end{equation*}
$$

T hus, we get the condition for the existence of a giant com ponent in this graph:

$$
\begin{aligned}
& \frac{\mathrm{R}(\mathrm{R} \quad 1) \mathrm{b}}{\mathrm{Rb}}>\frac{1}{2}
\end{aligned}
$$

A fter sim plifying the above equation, the condition is:

$$
\begin{equation*}
\mathrm{b}>\frac{1}{\mathrm{~N}^{2} 3 \mathrm{~N}} \tag{14}
\end{equation*}
$$

Since we w ill com pare this graph w ith an E rdosRenyi random graph with the sam e average degree hki, we express the condition for the existence of giant com ponent in term s of the average degree given by Equation $\overline{14} 1$

$$
\begin{equation*}
\mathrm{hki}>1+\frac{2}{\mathrm{~N}^{2} 3 \mathrm{~N}} \tag{15}
\end{equation*}
$$

As N ! 1 , the condition is hki> 1. An interesting point is that this is exactly where the phase transition occurs in an E rdosRenyi graph. Therefore, the requirem ent that all edges be transitive does not delay the appearance of the giant com ponent. It does how ever have a tem pering e ect on the rate ofgrow th of the giant com ponent as we will see below.

W hen a giant com ponent exists in the graph and the probability for a node to whom A is connected to not belong to it is $s$, the size of the giant com ponent is given by:

$$
\begin{array}{rlrl}
S & =1 \quad G_{0}\left(S_{0}\right) \\
& =1 \quad X^{2} \quad r_{m}\left(s_{0}^{2}\right)^{m} \\
& =1 & m=0 \\
& \left(b s^{2}+1\right. & b)^{R}
\end{array}
$$

$w$ here $s_{0}$ is the solution of the function:

$$
\begin{align*}
s & =G_{1}(s)  \tag{19}\\
& =X^{X^{1}} m r_{m}\left(s^{2}\right)^{m^{1}}  \tag{20}\\
& =\left(b s^{2}+1 \quad b\right)^{R 1} \tag{21}
\end{align*}
$$

A s we have assum ed $S>0$, we know that $s m$ ust be som e value larger than 0 and $s m$ aller than 1 , and thus $s=1$ is a trivial solution of the function.

F IG . 6: C om parison of num erical sim ulations w ith analytical solutions for the fraction of the netw ork occupied by the giant com ponent of a 10,000 node triangle graph and the corresp onding E rdos $R$ enyi graph

W e com pare the solution $s_{0}$ to num erical sim ulations of netw orks of random triangles. E ach netw ork contains $\mathrm{N}=10 ; 000$ nodes, and we select M random triangles to connect from the $N$ nodes. Foreach value ofM we generate 50 random netw orks and average the size of the giant com ponent. The results, show n in $F$ igure ${ }_{6}^{\bar{G}}$, show excellent agreem ent betw een the analyticalprediction and the num erical sim ulation. For com parison, we show both the num erical prediction and analytical result for the size of the giant com ponent in an E rdosRenyi random graph w ith the sam e num ber of nodes and edges. T he size of the giant com ponent in the E rdosR enyigraph is given by the solution $s$ to the equation $s=1 \exp (h k i s) .>$ From the gure, we can see that as average degree grow $s$, the phase transitions of the transitive graph and the random graph occur at the sam e tim e, while the size ofgiant com ponent of the E rdos $R$ enyi graph grow sm ore quidkly as we increase the average degree. A $n$ intuitive explanation is that in an ErdosRenyi graph one need not expend a closure' edge to close a triad. R ather, that edge can be used to connect a disconnected node or sm allcom ponent to the giant com ponent.

The fact that the phase transition occurs at the sam e average degree for both the E rdos $R$ enyi and transitive netw ork show s that the requirem ent of transitivity does not result in a need for increased average connectivity in order for the giant com ponent to form . N ote that the phase transition in our $m$ odel, where all edges are the result of the addition of triangles, is quite di erent from what it is in a graph that would result from taking a sim ple E rdosR enyi graph and rem oving all edges that do not fall w ithin a triangle. In the E rdosRenyi graph w th non-transitive edge rem oval the percolation threshold occurs at a degree that scales as $\mathrm{N}^{\frac{1}{3}}$.

This condition for the giant com ponent in an E rdosRenyi graph w th weak ties rem oved can be derived as
follow s. A giant com ponent of strong tries form s when, after arriving at an arbitrary triangle $T$, the expected value of the num ber other adjacent triangles that one could $\backslash m$ ove to" is equal to 1 . T he probability that there is a triangle $T^{0}$ adjacent to $T$ that is not the triangle from which we reached $T$ is given by $2{ }^{N}{ }_{2}^{5} p^{3}$. There are ${ }^{N}{ }_{2}^{5}$ choioes for the vertices in $T^{0}$ not shared $w$ ith $T$, and two choices of the vertex shared by $T$ and $T^{0}$ (excluding the vertex of $T$ that is shared $w$ th the triangle we arrived from ). $\mathrm{p}=\mathrm{hki}=\mathrm{N}$ is the probability that any two vertices in an E rdosRenyigraph share an edge. Thus when N is large, the average degree at the phase transition is $h k i=N^{1=3}$. In several real w orld networks the average degree was found to vary as $N$ where $0 \quad 0: 3 \bar{i}\left[\overline{1}_{11}^{1} 0\right]$. But in a random netw ork, this density falls short of the $\mathrm{N}^{1=3}$ necessary to m ake the accidental occurrence of closed triads (and therefore strong ties) high enough for the netw ork to percolate.

If one further requires that the triangles overlap not just in one node but in two, as in the percolation of $k$ cliques [lill the phase transition occurs at a critical average degree that grow $s$ as $N^{\frac{k 2}{k-1}}$, with $k=3$. This $m$ eans that the average degree has to grow in linear proportion to $N$ in order for a giant com ponent to form. Together, these two results show that the ErdosRenyi random graph typically does not contain su ciently nu$m$ erous strong ties to percolate. But as we have shown in section II, realw orld social netw orks do contain $m$ any strong ties that percolate. This can be intuitively explained by the observation that new social ties typically form in the context of geographicaland socioculturalsettings [19]. In these contexts it is natural that the ties tend to form closed triads rather than being added independently, as they are in E rdos $R$ enyirandom graphs.

## IV. AVERAGESHORTEST PATH

E xact results for the average shortest path are di cult to derive even for a random graph. W e therefore used num erical sim ulations to $m$ easure the average shortest path betw een all reachable nodes as we increase the size of the netw ork. W e selected a value of the average node degree where the giant com ponent existed, but did not take up all of the graph. At our chosen value, $M=$ $0: 5 \mathrm{~N}$, there are tw ice as m any triangles as nodes. This constant proportion of triangles to nodes $m$ eans that $b$, the probability of any triple of nodes being connected, falls as $1=\mathrm{N}^{2}$.

At M $=0: 5 \mathrm{~N}$, the giant com ponent occupies $76 \%$ of the nodes, while in the equivalent random graph it takes up $94 \%$ of the nodes. This $m$ akes it di cult to directly com pare the two netw orks, since the average shortest path ism easured betw een reachable pairs, and the E rdosRenyigraph has m ore of them. Figure ${ }_{1}^{17}$, show $s$ that the average shortest path is actually shorter in the triangle graph. This $m$ ay be explained by the fact that there are few er nodes in the giant com ponent but a greater density
of links. O nce we consider the average shortest path relative to the size of the giant com ponent, the curves becom e nearly identical for both netw orks. This show s that the requirem ent of triadic closure does not negatively im pact the average shortest path for reachable pairs, but those pairs are few er in num ber.

FIG.7: N um erical com parison of the average shortest path in triangle graphs and E rdosR enyi graphs w ith the sam e num ber of nodes and edges. The inset show s the average shortest path as a function of the size of the giant com ponent rather than the total num ber of nodes.

## V. CONCLUSIONSAND FUTUREWORK

In this paper we study the connectivity of strong ties in netw orks, where strong ties are de ned as belonging to closed triads. W e nd that tw o real w orld social netw orks are robust w ith respect to rem oval of weak links, in the sense that there rem ains a giant com ponent that is sm allerbut stilloccupies a m a jority of the graph. W e also nd em pirically that the rem ovalof weak links lengthens the average shortest path $m$ odestly. In com parison, the rem oval of weak links in an W S sm all world netw ork or an E rdosRenyigraph would isolate the vast $m$ a jority of nodes. It is the high clustering of social netw orks that allow $s$ them to transm it or gather inform ation via strong ties.

W e also pose a basic question, which is the cost paid for the requirem ent of transitive ties in term $s$ of the size of the giant com ponent and the length of the average shortest path. We consider the sim plest random graph m odel consisting entirely of closed triads and com pare it to a netw ork where the links are random ly rew ired. W e nd that the giant com ponent occurs at the sam e point| when the average node degree equals 1. H ow ever, past the phase transition, the giant com ponent in the graph of closed triads grow s m ore slow ly than it does in the random netw ork. W e further exam ine the dependence of the average shortest path $w$ th the size of the netw ork and
nd it to be alm ost identical for reachable pairs in both the triangle graph and the equivalent random netw ork.

A $n$ unansw ered question is whetherm ore sophisticated
 nom enon of strong ties that can be linked together to span an entire netw ork. In particular, in future work we are interested in exam ining the strong tie properties of social netw orks where the edge probabilities depend on the hierarchial organization of underlying social dim en-
sions.
