Germanosilicides, especially those formed on compressive substrates, are less stable than silicides against agglomeration. By studying the solid-state reaction of Ni thin film on strained $Si_{0.8}Ge_{0.2}(001)$, we show that nickel germanosilicide is different from nickel silicide and nickel germanide in several respects: the grains are smaller and faceted, the groove angle is sharper, and dealloying takes place. The germanium out-diffusion creates a stress in the film which favors grooving and agglomeration.

 $Si_{1-x}Ge_x$ alloys are under consideration for a wide variety of high performance electronic and optoelectronic devices, including advanced metal-oxide-semiconductor field-effect transistors (MOSFETs), where the enhanced carrier mobility of Ge (channel) and the reduced contact resistance (source and drain) are particularly important. Reliable low-resistivity electrical contacts to the Ge-containing regions can be formed using the same process as for self-aligned silicides. NiSi_{1-x}Ge_x is the contact of choice in such applications due to its lowresistivity and the low processing temperature needed for its formation. Interfacial reactions of Ni with Si_{1-x}Ge_x have been studied in the context of ohmic contacts and Schottky barriers for infrared detectors.¹⁻⁴ The downside of metal germanosilicides is their lower stability against agglomeration than the corresponding silicides.⁵⁻⁸ Moreover, germanosilicide films formed on compressive substrates are less stable than those formed on relaxed substrates.⁵⁻⁷ There is a tendency for increased Ge content of the $Si_{1-x}Ge_x$ alloy at the triple junction, i.e. the intersection of the semiconductor/germanosilicide interface and the grain boundary.^{1, 5, 7–9} In this letter, we examine the correlations between agglomeration, composition inhomogeneities and interface morphology in NiSi_{1-x}Ge_x films¹⁰ formed on Si_{0.8}Ge_{0.2}. We demonstrate that germanosilicides exhibit a fundamentally different agglomeration mechanism than the corresponding silicide and germanide films.

Nickel films (15 nm thick) were DC magnetron sputtered (base pressure $< 5 \times 10^{-7}$ torr) onto a 73 nm-thick strained Si_{0.8}Ge_{0.2}(001). Rapid thermal annealing (RTA) in a N₂ ambient for 20 s between 300 and 800 °C was employed to form the nickel germanosilicide. X-ray diffraction (not shown) indicates that only NiSi_{1-x}Ge_x was formed during RTA at 400–800 °C. At 300 °C both Ni₂Si_{1-x}Ge_x and NiSi_{1-x}Ge_x were found.

Figure 1(a) is a high-resolution cross-sectional transmission electron micrograph (HRXTEM) of NiSi_{1-x}Ge_x/Si_{0.8}Ge_{0.2} after RTA at 500 °C. A well-defined groove forms at the (triple) junction of the NiSi_{1-x}Ge_x grain boundary and the NiSi_{1-x}Ge_x/Si_{1-x}Ge_x interface (the grain boundary groove at the free surface is very shallow). Similarly, grooves form at grain boundaries in NiSi on Si and NiGe on Ge, as shown in Figs. 1(b) and 1(c). The grain boundary groove angle θ (defined in Fig. 1) in NiSi_{1-x}Ge_x is considerably smaller than in NiSi and NiGe (the latter two are of similar magnitude).

Figure 2(a) shows a cross-sectional transmission electron micrograph of NiSi_{1-x}Ge_x formed on compressive Si_{0.8}Ge_{0.2} at a lower magnification than that in Fig. 1(a). The NiSi_{1-x}Ge_x/Si_{1-x}Ge_x interface in this figure consists of a series of nearly flat sections, joined at relatively sharp corners. A large section of this interface appears to remain parallel to the initial flat (001) surface of the Si_{1-x}Ge_x substrate. Although the possible importance of this phenomenon has not previously been emphasized, polygonal NiSi_{1-x}Ge_x interface morphologies can also be observed in earlier studies.^{5, 6, 9, 11} On the other hand, the NiSi/Si and NiGe/Ge interfaces appear to be much smoother curves (i.e., of nearly constant curvature), as shown by Figs. 2(b) and 2(c). Constant curvature interfaces meeting at grain boundary grooves suggest that capillary equilibrium was established over the entire interface (assuming isotropic incoherent interface energies).

Sheet resistance measurements (not shown) indicate that the resistivity of the $NiSi_{1-x}Ge_x$ increasing with RTA temperature above 500°C. Since the x-ray diffraction data indicate that these films contained only one phase, the increasing sheet resistance must be associated with agglomeration (rather than the formation of a high resistivity phase). This interpretation is supported by the plan view scanning electron micrographs (SEM) of Figs.

3(a) and 3(b) which show that little $NiSi_{1-x}Ge_x$ agglomeration has occurred at 500°C and substantial agglomeration has occurred at 650°C.

Comparison of the sheet resistance data for NiSi_{1-x}Ge_x formed on strained Si_{0.8}Ge_{0.2} with that of NiSi on Si suggests that agglomeration begins at temperatures below 500°C in the germanosilicide whereas NiSi films (same thickness and annealing time, 20 s) show little agglomeration to temperatures 100°C higher. This is supported by the SEM micrographs of the NiSi_{1-x}Ge_x and NiSi agglomeration morphologies in Fig. 3. These micrographs also show that the gaps in the NiSi_{1-x}Ge_x are uniformly spaced with a separation comparable with the grain size, while in the NiSi, the hole spacing is non-uniform and several times larger than the grain size. NiGe films on Ge, Fig. 2(d), exhibit a morphology very similar to that of NiSi on Si at a similar degree of agglomeration, Fig. 2(c). This is supprising, since one would expect that the behavior of the NiSi_{1-x}Ge_x should be intermediate between those of NiGe and NiSi.

The results presented above, taken *in toto*, suggest that the grooving, interface morphology, and agglomeration properties of NiSi_{1-x}Ge_x are quite different from those of NiSi and NiGe. Clearly, a major difference between them is that the germanosilicide is a solid solution alloy. As such, the thermodynamics of the system is strongly influenced by alloy thermodynamics rather than just interface energies (the normal basis for discussions of agglomeration). In fact, it may be that the variation of composition and its influence on the thermodynamics and kinetics of the system is responsible for the differences between the NiSi_{1-x}Ge_x and its terminal phases NiSi and NiGe. To this end, we employed energy dispersive x-ray spectroscopy (TEM-EDX) to determine the relative concentrations of Si and Ge at different locations in the microstructure (labeled S1–S8 in Fig. 1(a)).

Each EDX measurement averages over a cylinder of material of approximate diameter 5 nm. The results, shown in Fig. 1(d), suggest that the Ge content of the $Si_{1-x}Ge_x$ alloy and the $NiSi_{1-x}Ge_x$ film are indistinguishable at all locations in these two materials that are not near the grain boundary (spots S1, S4, S5, S7, and S8). Interestingly, the Ge concentration is reduced by approximately a factor of three near the grain boundary in the $NiSi_{1-x}Ge_x$ (spot S2). The Ge concentration in the $Si_{1-x}Ge_x$ alloy immediately below the triple junction (spot S3) is increased by more than a factor of two. Similar observations were made in the Ti– $Si_{1-x}Ge_x$ system.¹² This suggests that the $NiSi_{1-x}Ge_x$ film was formed sufficiently rapidly that there was little time for Si/Ge redistribution and that the Ge depleted from the $NiSi_{1-x}Ge_x$ flowed down the grain boundary toward the triple junction with $Si_{1-x}Ge_x$. The triple junction moves up, trapping the high concentration of Ge along its track.

In the Ni–Si–Ge phase diagram,⁸ the tie-lines connect regions with composition near $NiSi_{0.8}Ge_{0.2}$ with regions with compositions near $Si_{0.3}Ge_{0.7}$ at 600 °C. Therefore, as the film/substrate systems evolves, the germanosilicide will expel germanium into the silicon-germanium. Since Ge diffusion is faster along the $NiSi_{1-x}Ge_x$ grain boundary than within a $NiSi_{1-x}Ge_x$ grain the grain boundary is the fastest path for Ge egress. This explains why the region near the grain boundary in the germanosilicide is Ge-poor compared with the rest of the germanosilicide film (see Fig. 1). Since the expelled Ge enters the $Si_{1-x}Ge_x$ directly under the germanosilicide grain boundary, this region should be richer in Ge than the rest of the substrate, as also seen in Fig. 1.

The morphology of the grain boundary groove in $NiSi_{1-x}Ge_x$ is quite different from those in NiGe and NiSi. In the latter cases, the film/substrate interfaces are uniformly curved while the groove has more abrupt features in $NiSi_{1-x}Ge_x$ (see Fig. 2). This is consistent with

the much faster grooving seen in NiSi_{1-x}Ge_x, i.e. when grooving is fast there is not sufficient time available to diffusionally smooth the interfaces. We also note that the apparent groove angle θ is significantly smaller in NiSi_{1-x}Ge_x than in NiSi or NiGe (see Fig. 1). Since NiSi_{1-x}Ge_x (Si_{1-x}Ge_x) are continuous solid solutions between NiSi and NiGe (Si and Ge), we expect that the grain boundary and interface energies are also smooth interpolations between these limits. Therefore, it is doubtful that this large angle change is associated with differences in the interface/grain boundary energies. Rather, we suggest that the morphology observed during the grain boundary grooving in NiSi_{1-x}Ge_x is kinetically determined (i.e. the triple junction angle *observed at this scale* is not the equilibrium angle). While Ge diffusion can change the compositions of the two phases, it is only transport of the Ni that controls morphology change (we note that the solubilities of Ni in Si_{1-x}Ge_x and NiSi_{1-x}Ge_x are negligible).

The difference in groove morphology between the NiSi, NiGe, and NiSi_{1-x}Ge_x is likely associated with the fact that of these three, only in NiSi_{1-x}Ge_x does the composition vary. Germanium diffuses down the NiSi_{1-x}Ge_x grain boundary, as shown in Fig. 4(a), at the same time as the film grooves. This leads to a depletion of Ge and a tensile stress in the film (the atomic volume of nickel silicide is 10% lower than that of nickel germanide) as shown in Fig. 4(b). Conversely the substrate is under compression just below the triple junction since the lattice parameter of Si_{1-x}Ge_x increases with Ge content. Formation of new NiSi_{1-x}Ge_x at the grain boundary in the film would relieve the tensile stress in the film. This requires shortrange Ni diffusion along the grain boundary, Fig. 4(c). (Note, there will also be diffusion of Ni along the interface to remove gradients in interface curvature.) This should occur readily given the fast out-diffusion of Ge and in-diffusion of Si along the grain boundary. Hence, the fast grooving can ultimately be traced to the grain boundary diffusion of Ge out of the $NiSi_{1-x}Ge_x$ film. This mechanism does not replace the "usual" grooving mechanism observed in NiSi and NiGe.¹³ The two effects combine and lead to faster agglomeration in nickel germanosilicide than in the silicide or germanide. If the grain boundary and interface energies were small the "usual" grooving mechanism would be very slow but the mechanism presented would still work as it does not depend on these energies.

In summary, we demonstrated that the agglomeration of nickel germanosilicide is fundamentally different from that in NiSi and NiGe: it occurs more quickly, it leads to very different grooving morphologies, and composition changes. Of particular importance is the coupling between the change in alloy composition that occurs through fast grain boundary diffusion and the acceleration of grooving associated with inhomogeneous compositional stress effects. The fast grooving in NiSi_{1-x}Ge_x leads to groove morphologies that are much farther from equilibrium than in NiSi or NiGe (non-uniform interface curvature). The composition changes that occur in NiSi_{1-x}Ge_x are the cause of the widely observed acceleration of agglomeration in this system.
