Abstract. We present new algorithm for growth of non-clustered planar graphs by aggregation of cells with given distribution of size and constraint of connectivity $k = 3$ per node. The emergent graph structures are controlled by two parameters: chemical potential of the cell aggregation and the width of the cell size distribution. We compute several statistical properties of these graphs: fractal dimension of the perimeter, distribution of shortest paths between pairs of nodes and topological betweenness of nodes and links. We show how these topological properties depend on the control parameters of the aggregation process and discuss their relevance for the conduction of current in self-assembled nanopatterns.

1 Introduction

In recent years increased interests in various networks realizations [1,2] revealed that several new types of graphs termed structured graphs are more appropriate mathematical objects to describe complex network's geometry than traditional random graphs [3]. The variety of structures was found to emerge through evolution processes in which nodes and links are added sequentially according to specified rules, in particular, the preferential attachment rules lead to strongly inhomogeneous scale-free graphs [1]. In contrast to the evolving networks, which comprise a class of causal graphs, the class of homogeneous graphs consists of graphs with fixed number of nodes and fluctuating or rewiring links according to given rules or certain optimization processes. Complex graph structures may emerge in this procedures, especially when certain global or local optimization constraints are imposed [4].

Planar graphs are special class of graphs that can be embedded in a Euclidean plane. A graph is planar if it does not contain a subdivision of K_5 (5-clique) and $K_{3,3}$ (minimal non-planar graph with 6 nodes) [3]. Consequently, planar graphs fulfill Euler's law: $N_p + N = E + 1$, which is relating the number of nodes N , links E and polygons N_p .

In this work we suggest a new method for growing a planar cellular graph by attachment of objects (cells (polygons) of length n_p , which are chosen from a given distribution $f(n_p)$). The polygons are added sequentially in time starting from an initial polygon. In addition, we strictly impose the constraint on number

of links per node $k = 3$, which is thus fulfilled everywhere in the interior of the graph and on some nodes on the graph boundary. The attachment of cells is controlled by two parameters: the width of the distribution of cell sizes σ and the parameter ϕ that plays the role of chemical potential of cell aggregation. In the limit of vanishing attachment potential $\phi \rightarrow 0$ the growth process resembles the one in diffusion-limited aggregation [6]. However, aggregated are spatially extended cells of particles rather than single particles.

Emergent structures of cellular networks are resembling of soap froths [7] or patterns of nano-particles self-assembled through nonlinear dynamic processes [8,9]. Typically, a pattern of cells appears when nano-particles are immersed in a liquid film, which is then allowed to evaporate until holes of different sizes open-up leaving particles in the walls between the holes [9,10]. Generally, the structure of the patterns reflects the physical processes on them, such as current transport [11]. It is therefore important to understand the topology of the aggregated cellular networks in detail. Here we study the topological properties, such as shortest paths between nodes, topological centrality, and fractality of the graph's perimeter in different cellular networks obtained by varying the control parameters of the aggregation processes.

2 Cell Aggregation

The basic idea is to make growing model of planar graph with given distribution of cell (polygon) sizes $f(n_p)$ and with degree of nodes $2 \leq k \leq 3$.

2.1 Topological constraint

For this purpose we observe some topological constraints on the distribution of cell sizes: (i) $f(n_p)$ is defined for $n_p \geq 3$, for non-clustered graph we require $f(3) = 0$; (ii) planar graph obeys Euler's law: $N_p + N = E + 1$. Among these the homogeneous plane-filling structures are of special interest [7]. For this class of graphs majority of nodes are in the interior of the graph, i.e., nodes with degree $k = 3$. Therefore $3N = 2E$ and Euler's law becomes

$$6N_p = 2E + 6: \quad (1)$$

For large system with distribution of cell sizes $f(n_p)$ we have

$$N = N_p \sum_{n_p} \frac{n_p f(n_p)}{3}; E = N_p \sum_{n_p} \frac{n_p f(n_p)}{2}: \quad (2)$$

Substituting second relation into (1): $6N_p = N_p \sum_{n_p} n_p f(n_p) + 6$, then for large $N_p \gg 1$ one can find that the average cell size is equal to six

$$\sum_{n_p} n_p f(n_p) = 6: \quad (3)$$

We use lognormal distribution of polygon size

$$f(n_p) = \frac{1}{s} \frac{1}{x} e^{-\frac{\ln^2 x - x_0}{2s^2}}; \quad (4)$$

which is most often found in experiments [9]. Using the condition (3) the number of independent parameters in (4) is reduced

$$\ln p_i = 6 \quad) \quad x_0 = 6e^{s^2/2}; s^2 = \ln 1 + \frac{2}{36}; \quad (5)$$

where second central moment s^2 remains as the control parameter in our case.

2.2 Model

Starting from an initial cell, at each time step a new cell with size taken from the distribution $f(n_p)$ is attached to the graph boundary of the graph according to the following rules:

1. In the aggregation only nodes with degree 3 can be closed inside the graph;
2. New link can be assigned only to nodes with degree 2;
3. Potential nesting place is searched as an array of nodes on graph boundary with degree 3 limited with two nodes of degree 2. The nested part of the cell is identified with the nodes of the nesting string. Therefore, number of extra nodes to be added is $n = n_p - 1$, where l is length of the nesting string. We select the nesting place with probability $p = e^{-n}$, where the parameter plays the role of the chemical potential for addition of new nodes.

Fig.1. Two possible types of cell-aggregated planar graphs: open and closed structures, obtained by lognormal distribution with $s^2 = 1.0$, and aggregation potential $\mu = 5.0$.

We implemented this algorithm in C++ according to following steps:

```

Initial graph: one polygon of size  $n_p$  taken from  $f(n_p)$ 
For  $i=2$  to  $N_p$ 
     $n_p$  = next random from distribution  $f(n_p)$ 
    If (there is no nodes on graph boundary with degree 2) exit(1)
    For all  $j$ =(periphery node with degree 2)
         $d$ =distance to the next node on graph boundary with degree 2
        Number of new nodes  $n = n_p-d-1$ 
        If ( $n>0$ )  $p(j)=\exp(-\alpha n)$ 
    End of loop  $j$ 
    If (there is no  $j$  with  $n>0$ ) exit(2)
    Normalize  $p(j)$ 
     $j$  = next random from distribution  $p(j)$ 
    Add new polygon with size  $n_p$  linked with
        node  $j$  and next node on graph boundary with degree 2
End of loop  $i$ 
exit(0)

```

Depending on model parameters of the growth process and its stochasticity three possible exit cases are:

```

{ exit(0) -Open structure (planar graph with  $N_p$  polygons);
{ exit(1) -Closed structure (after some number of step there are no more nodes
of degree 2 and structure stops to grow, no nesting places of any size);
{ exit(2) -No nesting place available for current cell. In this case one can take
next cell, which in turn perturbs the actual distribution.

```

We never experienced the exit(2) situation for the range of parameters $\alpha \in [0.5; 2.0]$, $\beta \in [0; 5]$ and $N_p = 1000$ in huge number of samples. Two examples of the emergent open and closed structures are shown on Fig. 1. More examples of cellular networks are shown in Fig. 2 for varying parameters α and β .

3 Fractal Dimension of Network Perimeter

During the nesting growing process in one step number of nodes N increases by $n < n_p$. Number of added nodes n at each step depends on the cell size and length of the nesting string. Therefore, $N \propto N_p$ where $\alpha = \ln n$ is average growth rate. For open structures (see Fig. 1-2) boundary of the graph becomes fractal, depending on the control parameters. In fact, length of the graph boundary L grows as a power of the number of cells N_p (or network size N) with fractal dimension D defined by $L \propto N_p^D$.

In Fig. 3 we show how number of nodes on the graph boundary increases with N_p . Each point is averaged over 10 emergent growing networks. The dimension D is in the range $\frac{1}{2} \leq D \leq 1$, when $D = 1$ correspond to structures of high fractality, that is obtained for small values of the parameter α . $D = \frac{1}{2}$ correspond to planar "circle like" structures with reduced fractality. For $\alpha > 0$ we observe a

Fig.2. Cell-aggregated planar graphs with lognormal distribution of polygon size for various values of width β_2 and cell aggregation potential v . Width of lines represent topological betweenness (centrality) of links calculated in Section 4.2.

Fig.3. Scaling of the network perimeter for (a) $\beta_2 = 0$ hexagons only (b) $\beta_2 = 2$.

continuous crossover between these two limits (see Fig.3b for $\beta_2 = 2$). However, in structures with homogeneous cell distribution ($\beta_2 = 0$ – hexagons only) a sharp transition seems to occur at $\beta_c \approx 1.5$.

4 Shortest Paths and Centrality on Cellular Networks

In this section we consider global topological properties of the cell-aggregated planar graphs and their dependence on the control parameters β_2 and β_3 .

4.1 Shortest Paths

Shortest path between two nodes is defined as path along the smallest number of intermediate links [3]. We implemented an algorithm for counting shortest paths of Dijkstra type [12]. In Fig. 4 we show distribution of lengths of shortest paths between all pairs of nodes on network. All networks are for fixed $\beta_2 = 1.0$ and approximately of the same size $N \approx 1000$ nodes. Each point in Fig. 4 is averaged over 100 sample networks. We found similar results for other β_2 values.

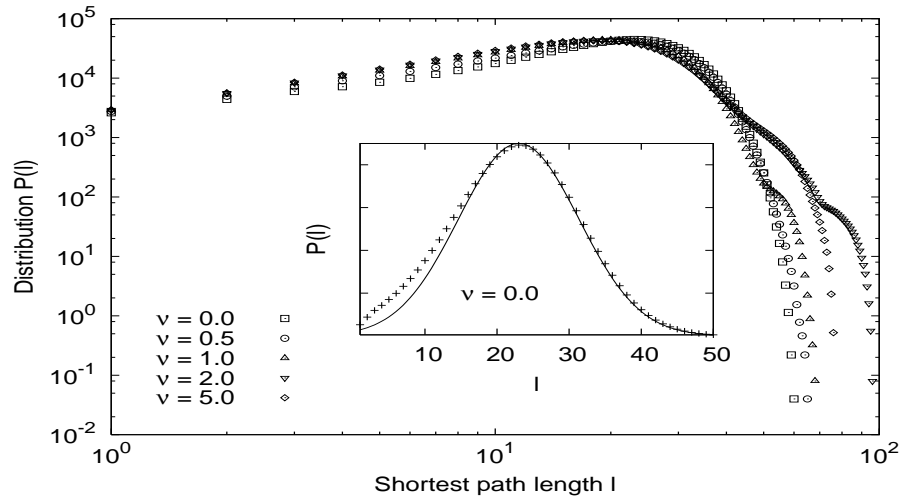

Fig. 4. Distribution of lengths of shortest paths on networks for fixed $\beta_2 = 1.0$ and various values of β_3 . Insert: The distribution in the case $\beta_3 = 0$ is shown on linear scale. Solid line: Gaussian with $l_0 = 23$ and $\sigma = 8.37$.

All these networks have similar topology at local level, because the number of links at all interior nodes is constant $k = 3$. Therefore, distributions of shortest distances at small scale are similar for all values of parameter β_3 . Differences in global topology appear on large scale for lengths larger than peak value $l_0 \approx 25$, which manifest in occurrence of additional peaks (see Fig. 4). The probability of long paths increases for larger values of the parameter β_3 . Whereas in the limit $\beta_3 = 0$ the distribution of length of shortest paths on large scale can be approximated with a normal distribution (inset on Fig. 4).

4.2 Centrality Measures

Betweenness centrality of a node in network is defined by [13,3]

$$C_B(v) = \sum_{s \neq v \neq t} \frac{\sigma_{st}(v)}{\sigma_{st}} \quad (6)$$

where σ_{st} is total number of shortest paths between nodes s and t , and $\sigma_{st}(v)$ is number of these paths that node v lies on. Betweenness of links is defined in analogous way. In our algorithm, we record number of shortest paths through each node and through each link on a network. In Fig. 5 we show distributions of betweenness of nodes and links averaged over 100 sample networks with fixed $\mu_2 = 1.0$ and size $N = 1000$ nodes. For inhomogeneous networks, distributions

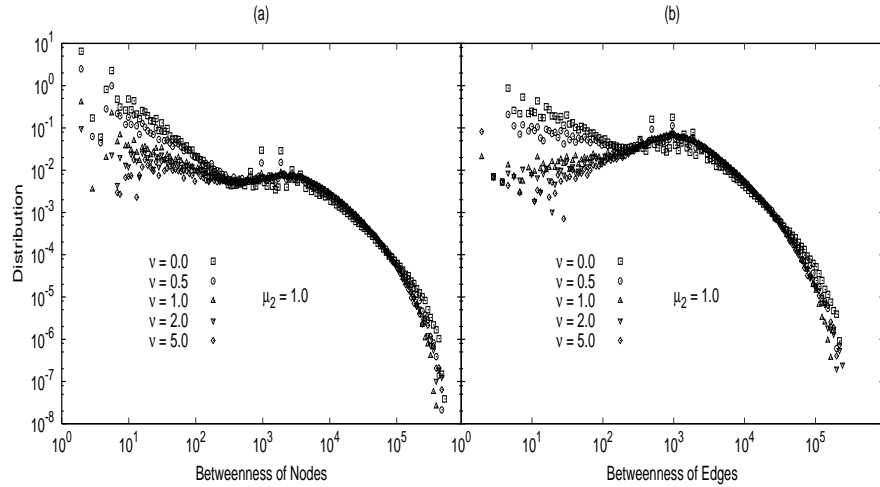

Fig. 5. Distribution of betweenness (a) of nodes (b) of links.

of these two betweenness measures can be substantially different. In our case, however, they are similar because all interior nodes have fixed degree $k = 3$. We find that distributions at small scale strongly depend on parameter μ , which results from the graph boundary. Similar conclusions hold for other μ_2 values.

In Fig. 2 thick lines represent links with large betweenness. For this type of networks the strongest lines, which make the skeleton of the graph, are connecting the nodes with largest centrality measure.

5 Conclusions

We have introduced a new algorithm for growth of graphs by aggregation process of extended objects – polygons with size distribution. Depending on aggregation conditions, which are determined by two parameters controlling the distribution width and attachment potential, we can get a wide spectrum of emergent structures. In this paper we presented some results for the case of lognormal distribution of cells and additional constraints, leading to the emergent non-clustered planar graphs with a constant node connectivity. The algorithm works for variety of cell distributions and constraints, that may result in diverse opened (fractal) or closed structures. For instance, for a special set of parameters we can get closed structures of C_{60} type.

We measured several topological properties of these networks in quantitative details| fractality of the graph boundary, shortest paths, and betweenness centrality. These properties are important for some dynamical process on networks such as electrical conductivity [11] via single electron tunneling [9,14].
