## Abstract

We propose a new algorithm for sampling the  $N$ -body density  $\rho(\mathbf{R}) = \int_{\mathbb{R}^{3N}} \rho(\mathbf{R}, \mathbf{P})$  in the Variational Monte Carlo (VMC) framework. This algorithm is based upon a modified Ricci-Ciccotti discretization of the Langevin dynamics in the phase space  $(\mathbf{R}; \mathbf{P})$  improved by a Metropolis acceptance/rejection step. We show through some representative numerical examples (Lithium, Fluorine and Copper atoms, and phenol molecule), that this algorithm is superior to the standard sampling algorithm based on the biased random walk (importance sampling).

# I. INTRODUCTION

Most quantities of interest in quantum physics and chemistry are expectation values of the form

$$\frac{\langle \psi | \hat{O} | \psi \rangle}{\langle \psi | \psi \rangle} \quad (1)$$

where  $\hat{O}$  is the self-adjoint operator (the observable) associated with a physical quantity  $O$  and  $\psi$  a given wave function.

For  $N$ -body systems in the position representation,  $\psi$  is a function of  $3N$  real variables and

$$\frac{\langle \psi | \hat{O} | \psi \rangle}{\langle \psi | \psi \rangle} = \frac{\int_{\mathbb{R}^{3N}} \hat{O}(\mathbf{R}) |\psi(\mathbf{R})|^2 d\mathbf{R}}{\int_{\mathbb{R}^{3N}} |\psi(\mathbf{R})|^2 d\mathbf{R}} \quad (2)$$

High-dimensional integrals are very difficult to evaluate numerically by standard integration rules. For specific operators  $\hat{O}$  and specific wave functions  $\psi$ , *e.g.* for electronic Hamiltonians and Slater determinants built from Gaussian atomic orbitals, the above integrals can be calculated analytically. In some other special cases, (2) can be rewritten in terms of integrals on lower-dimensional spaces (typically  $\mathbb{R}^3$  or  $\mathbb{R}^6$ ).

In the general case however, the only possible way to evaluate (2) is to resort to stochastic techniques. The VMC method [1] consists in remarking that

$$\frac{\langle \psi | \hat{O} | \psi \rangle}{\langle \psi | \psi \rangle} = \frac{\int_{\mathbb{R}^{3N}} O_L(\mathbf{R}) |\psi(\mathbf{R})|^2 d\mathbf{R}}{\int_{\mathbb{R}^{3N}} |\psi(\mathbf{R})|^2 d\mathbf{R}} \quad (3)$$

with  $O_L(\mathbf{R}) = \hat{O}(\mathbf{R}) / |\psi(\mathbf{R})|^2$ , hence that

$$\frac{\langle \psi | \hat{O} | \psi \rangle}{\langle \psi | \psi \rangle} = \frac{1}{L} \sum_{n=1}^L O_L(\mathbf{R}^n) \quad (4)$$

where  $\{\mathbf{R}^n\}_{n=1}^L$  are points of  $\mathbb{R}^{3N}$  drawn from the probability distribution  $\int_{\mathbb{R}^{3N}} |\psi(\mathbf{R})|^2 d\mathbf{R} = 1$ .

The VMC algorithms described in the present article are generic, in the sense that they can be used to compute the expectation value of any observable, for any  $N$ -body system. In the numerical example, we will however focus on the important case of the calculation of electronic energies of molecular systems. In this particular case, the expectation value to be

computed reads

$$\frac{\langle \psi | \hat{H} | \psi \rangle}{\langle \psi | \psi \rangle} = \frac{\int_{\mathbb{R}^{3N}} E_L(\mathbf{R}) |\psi(\mathbf{R})|^2 d\mathbf{R}}{\int_{\mathbb{R}^{3N}} |\psi(\mathbf{R})|^2 d\mathbf{R}} \quad (5)$$

where the scalar field  $E_L(\mathbf{R}) = \frac{\hat{H}\psi(\mathbf{R})}{\psi(\mathbf{R})}$  is called the *local energy*. Remark that if  $\psi$  is an eigenfunction of  $\hat{H}$  associated with the eigenvalue  $E$ ,  $E_L(\mathbf{R}) = E$  for all  $\mathbf{R}$ . Most often, VMC calculations are performed with trial wave functions  $\psi$  that are good approximations of some ground state wave function  $\psi_0$ . Consequently,  $E_L(\mathbf{R})$  usually is a function of low variance (with respect to the probability density  $|\psi(\mathbf{R})|^2 = \int_{\mathbb{R}^{3N}} |\psi(\mathbf{R})|^2$ ). This is the reason why, in practice, the approximation formula

$$\frac{\langle \psi | \hat{H} | \psi \rangle}{\langle \psi | \psi \rangle} \approx \frac{1}{L} \sum_{n=1}^L E_L(\mathbf{R}^n) \quad (6)$$

is fairly accurate, even for relatively small values of  $L$  (in practical applications on realistic molecular systems  $L$  ranges typically between  $10^6$  and  $10^9$ ).

Of course, the quality of the above approximation formula depends on the way the points  $(\mathbf{R}^n)_{n=1}^L$  are generated. In section II B, we describe the standard sampling method currently used for VMC calculations. It consists in a biased (or importance sampled) random walk in the configuration space (also called position space)  $\mathbb{R}^{3N}$  corrected by a Metropolis acceptance/rejection procedure. In section II C, we introduce a new sampling scheme in which the points  $(\mathbf{R}^n)_{n=1}^L$  are the projections on the configuration space of one realization of some Markov chain on the phase space (also called position-momentum space)  $\mathbb{R}^{3N} \times \mathbb{R}^{3N}$ . This Markov chain is obtained by a modified Langevin dynamics, corrected by a Metropolis acceptance/rejection procedure.

Finally, some numerical results are presented in section III. Various sampling algorithms are compared and it is demonstrated on a bench of representative examples that the algorithm proposed here based on the modified Langevin dynamics is the most efficient one (the mathematical criteria for measuring the efficiency will be made precise below).

Before turning to the technical details, let us briefly comment on the underlying motivations of our approach. The reason why we have introduced a (purely fictitious) Langevin dynamics in the VMC framework is twofold:

first, sampling methods based on Langevin dynamics turn out to outperform those

based on biased random walks in classical molecular dynamics (see [4] for a quantitative study on carbon chains);

second, a specific problem encountered in VMC calculations on fermionic systems is that the standard discretization of the biased random walk (Euler scheme) does not behave properly close to the nodal surface of the trial wave function. This is due to the fact that the drift term blows up as the inverse of the distance to the nodal surface: if a random walker gets close to the nodal surface, the drift term repulses it far apart in a single time step. As demonstrated in [7, 8], it is possible to partially circumvent this difficulty by resorting to more clever discretization schemes. Another strategy consists in replacing the biased random walk by a Langevin dynamics: the walkers then have a mass (hence some inertia) and the singular drift does not directly act on the position variables (as it is the case for the biased random walk), but indirectly *via* the momentum variables. The undesirable effects of the singularities are thus expected to be damped down.

## II. DESCRIPTION OF THE ALGORITHMS

### A. Metropolis algorithm

The Metropolis algorithm [3] is a general purpose sampling method, which combines the simulation of a Markov chain with an acceptance/rejection procedure.

In the present article, the underlying state space is either the configuration space  $\mathbb{R}^{3N}$  or the phase space  $\mathbb{R}^{3N} \times \mathbb{R}^{3N} = \mathbb{R}^{6N}$ . Recall that a Markov chain on  $\mathbb{R}^d$  is characterized by its transition kernel  $p$ . It is by definition the non-negative function of  $\mathbb{R}^d \times \mathcal{B}(\mathbb{R}^d) \times \mathcal{B}(\mathbb{R}^d)$  ( $\mathcal{B}(\mathbb{R}^d)$  is the set of all the Borel sets of  $\mathbb{R}^d$ ) such that, if  $X \in \mathbb{R}^d$  and  $B \in \mathcal{B}(\mathbb{R}^d)$ , the probability for the Markov chain to lay in  $B$  at step  $n + 1$  if it is at  $X$  at step  $n$  is  $p(X; B)$ . The transition kernel has a density with respect to the Lebesgue measure if for any  $X \in \mathbb{R}^d$ , there exists a non-negative function  $f_X \in L^1(\mathbb{R}^d)$  such that

$$p(X; B) = \int_B f_X(X^0) dX^0: \quad (7)$$

The non-negative number  $f_X(X^0)$  is often denoted by  $T(X^0; X)$  and the function  $T: \mathbb{R}^d \times \mathbb{R}^d \rightarrow \mathbb{R}_+$  is called the transition density.

Given a Markov chain on  $\mathbb{R}^d$  with transition density  $T$  and a positive function  $f \in L^1(\mathbb{R}^d)$ , the Metropolis algorithm consists in generating a sequence  $(X^n)_{n \geq 0}$  of points in  $\mathbb{R}^d$  starting from some point  $X^0 \in \mathbb{R}^d$  according to the following iterative procedure:

propose a move from  $X^n$  to  $X^{n+1}$  according to the transition density  $T(X^n \rightarrow X^{n+1})$ ;

compute the acceptance rate

$$A(X^n \rightarrow X^{n+1}) = \min \left\{ \frac{f(X^{n+1}) T(X^{n+1} \rightarrow X^n)}{f(X^n) T(X^n \rightarrow X^{n+1})}, 1 \right\};$$

draw a random variable  $U$  uniformly distributed in  $[0;1]$ ;

- if  $U \leq A(X^n \rightarrow X^{n+1})$ , accept the move:  $X^{n+1} = X^{n+1}$ ;
- if  $U > A(X^n \rightarrow X^{n+1})$ , reject the move:  $X^{n+1} = X^n$ .

It is not difficult to show (see [6] for instance) that, for a very large class of transition densities  $T$ , the points  $X^n$  generated by the Metropolis algorithm are asymptotically distributed according to the probability density  $f(x) = \int_{\mathbb{R}^d} f(x) dx$ . On the other hand, the practical efficiency of the algorithm crucially depends on the choice of the transition density (i.e. of the Markov chain).

## B. Random walks in the configuration space

In this section, the state space is the configuration space  $\mathbb{R}^{3N}$  and  $f = \int_{\mathbb{R}^d} f(x) dx$ , so that the Metropolis algorithm actually samples the probability density  $\int_{\mathbb{R}^{3N}} f(x) dx$ .

### 1. Simple random walk

In the original paper [3] of Metropolis *et al.*, the Markov chain is a simple random walk:

$$R^{n+1} = R^n + R U^n \tag{8}$$

where  $R$  is the step size and  $U^n$  are independent and identically distributed (i.i.d.) random vectors drawn uniformly in the  $3N$ -dimensional cube  $K = [-1;1]^{3N}$ . The corresponding transition density is  $T(R \rightarrow R^0) = \frac{1}{2^{3N}} \chi_K(R - R^0)$  where  $\chi_K$  is the characteristic function of the cube  $K$  (note that in this particular case,  $T(R \rightarrow R^0) = T(R^0 \rightarrow R)$ ).

## 2. Biased random walk

The simple random walk is far from being the optimal choice: it induces a high rejection rate, hence a large variance. A variance reduction technique usually referred to as the importance sampling method, consists in considering the so-called biased random walk or over-damped Langevin dynamics [11]:

$$d\mathbf{R}(t) = \tau [\log j(\mathbf{R}(t))] dt + d\mathbf{W}(t); \quad (9)$$

where  $\mathbf{W}(t)$  is a  $3N$ -dimensional Wiener process. Note that  $j(\mathbf{R})$  is an invariant measure of the Markov process (9), and, better, that the dynamics (9) is in fact ergodic and satisfies a detailed balance property [6]. The qualifier ergodic means that for any compactly supported continuous function  $g: \mathbb{R}^{3N} \rightarrow \mathbb{R}$ ,

$$\lim_{T \rightarrow \infty} \frac{1}{T} \int_0^T g(\mathbf{R}(t)) dt = \frac{\int_{\mathbb{R}^{3N}} g(\mathbf{R}) j(\mathbf{R}) d\mathbf{R}}{\int_{\mathbb{R}^{3N}} j(\mathbf{R}) d\mathbf{R}}; \quad (10)$$

The detailed balance property reads

$$j(\mathbf{R}) \int_{\mathbf{R}^0} T_\tau(\mathbf{R} \rightarrow \mathbf{R}^0) = j(\mathbf{R}^0) \int_{\mathbf{R}} T_\tau(\mathbf{R}^0 \rightarrow \mathbf{R}) \quad (11)$$

for any  $\tau > 0$ , where  $T_\tau(\mathbf{R} \rightarrow \mathbf{R}^0)$  is the probability density that the Markov process (9) is at  $\mathbf{R}^0$  at time  $t + \tau$  if it is at  $\mathbf{R}$  at time  $t$ . These above results are classical for regular, positive functions  $j$ , and have been recently proven for fermionic wave functions [14] (in the latter case, the dynamics is ergodic in each nodal pocket of the wave function  $j$ ).

Note that if one uses the Markov chain of density  $T_\tau(\mathbf{R} \rightarrow \mathbf{R}^0)$  in the Metropolis algorithm, the acceptance/rejection step is useless, since due to the detailed balance property, the acceptance rate always equals one.

The exact value of  $T_\tau(\mathbf{R} \rightarrow \mathbf{R}^0)$  being not known, a discretization of equation (9) with Euler scheme, is generally used

$$\mathbf{R}^{n+1} = \mathbf{R}^n + \tau \text{tr} [\log j(\mathbf{R}^n)] \mathbf{W}^n \quad (12)$$

where  $\mathbf{W}^n$  are i.i.d. Gaussian random vectors with zero mean and covariance matrix  $\tau \mathbf{I}_{3N}$  ( $\mathbf{I}_{3N}$  is the identity matrix). The Euler scheme leads to the approximated transition density

$$T_t^{\text{Euler}}(\mathbb{R}^0 \rightarrow \mathbb{R}^0) = \frac{1}{(2t)^{3N-2}} \exp \left[ \frac{\mathcal{R}^0(\mathbb{R}^0) - \text{tr}[\log j(\mathbb{R}^0)]}{2t} \right] \quad (13)$$

The time discretization introduces the so-called *time-step error*, whose consequence is that (12) samples  $j(\mathbb{R}^0) \stackrel{\mathbb{R}}{\approx} j(\mathbb{R}^{3N})$  *only approximately*. Note that the Metropolis acceptance/rejection procedure perfectly corrects the time-step error. In the limit  $t \rightarrow 0$ , the time-step error vanishes and the acceptance/rejection procedure is useless.

This sampling method is much more efficient than the Metropolis algorithm based on the simple random walk, since the Markov chain (12) does a large part of the work (it samples a short time-step approximation of  $j(\mathbb{R}^0) \stackrel{\mathbb{R}}{\approx} j(\mathbb{R}^{2N})$ ), which is clearly not the case for the simple random walk.

The standard method in VMC computations currently is the Metropolis algorithm based on the Markov chain defined by (12). For refinements of this method, we refer to [5, 9, 10].

### C. Random walks in the phase space

In this section, the state space is the phase space  $\mathbb{R}^{3N} \times \mathbb{R}^{3N}$ . Let us emphasize that the introduction of momentum variables is nothing but a numerical artifice. The phase space trajectories that will be dealt with in this section do not have any physical meaning.

#### 1. Langevin dynamics

The Langevin dynamics of a system of  $N$  particles of mass  $m$  evolving in an external potential  $V$  reads

$$\begin{aligned} \dot{\mathbf{R}}(t) &= \frac{1}{m} \mathbf{P}(t) dt; \\ \dot{\mathbf{P}}(t) &= -\nabla V(\mathbf{R}(t)) dt - \mathbf{P}(t) dt + d\mathbf{W}(t); \end{aligned} \quad (14)$$

As above,  $\mathbf{R}(t)$  is a  $3N$ -dimensional vector collecting the positions at time  $t$  of the  $N$  particles. The components of the  $3N$ -dimensional vector  $\mathbf{P}(t)$  are the corresponding momenta and  $\mathbf{W}(t)$  is a  $3N$ -dimensional Wiener process. The Langevin dynamics can be considered as a perturbation of the Newton dynamics (for which  $\gamma = 0$  and  $\xi = 0$ ). The magnitudes and  $\gamma$  of the random forces  $d\mathbf{W}(t)$  and of the drag term  $-\mathbf{P}(t) dt$  are related through the

fluctuation-dissipation formula

$$\beta^2 = \frac{2m}{\gamma}; \quad (15)$$

where  $\beta$  is the reciprocal temperature of the system. Let us underline that in the present setting,  $\gamma$  is a numerical parameter that is by no means related to the physical temperature of the system. It can be checked (at least for regular potentials  $V$ ) that the canonical distribution

$$d\mu(\mathbf{R}; \mathbf{P}) = Z^{-1} e^{-\beta H(\mathbf{R}, \mathbf{P})} d\mathbf{R} d\mathbf{P} \quad (16)$$

is an invariant probability measure for the system,  $Z$  being a normalization constant and

$$H(\mathbf{P}; \mathbf{R}) = V(\mathbf{R}) + \frac{\mathbf{P}^2}{2m} \quad (17)$$

being the Hamiltonian of the underlying Newton dynamics. In addition, the Langevin dynamics is ergodic (under some assumptions on  $V$ ). Thus, choosing

$$\beta = 1 \text{ and } V = -\log j^2, \quad (18)$$

the projection on the position space of the Langevin dynamics samples  $j^2(\mathbf{R}) \stackrel{R}{=} j^2$ . On the other hand, the Langevin dynamics does not satisfy the detailed balance property. We will come back to this important point in the forthcoming section.

In this context, the parameters  $m$  and  $\gamma$  (being then obtained through (15)) should be seen as numerical parameters to be optimized to get the best sampling. We now describe how to discretize and apply a Metropolis algorithm to the Langevin dynamics (14), in the context of VMC.

## 2. Time discretization of the Langevin dynamics

Many discretization schemes exist for Langevin dynamics. In order to choose which algorithm is best for VMC, we have tested four different schemes available in the literature [13, 15, 16, 17], with parameters  $\beta = 1$ ,  $\gamma = 1$  and  $m = 1$ . Our benchmark system is a Lithium atom, and a single determinantal wave function built upon Slater-type atomic orbitals, multiplied by a Jastrow factor. We turn off the acceptance/rejection step in these preliminary tests, since our purpose is to compare the time-step errors for the various algorithms. From the results displayed in table I, one can see that the Ricci-Ciccotti

algorithm [13] is the method which generates the smallest time-step error. This algorithm reads

$$\begin{aligned} \mathbf{R}^{n+1} &= \mathbf{R}^n + \frac{\tau}{m} \mathbf{P}^n \mathbf{e}^{-\tau/2} + \frac{\tau}{2m} \mathbf{r} \mathbf{V}(\mathbf{R}^n) \tau + \mathbf{G}^n \mathbf{e}^{-\tau/2}; \\ \mathbf{P}^{n+1} &= \mathbf{P}^n \mathbf{e}^{-\tau} - \frac{\tau}{2} \mathbf{r} \mathbf{V}(\mathbf{R}^n) + \mathbf{r} \mathbf{V}(\mathbf{R}^{n+1}) \mathbf{e}^{-\tau/2} + \mathbf{G}^n \mathbf{e}^{-\tau/2}; \end{aligned} \quad (19)$$

where  $\mathbf{G}^n$  are i.i.d. Gaussian random vectors with zero mean and variance  $2\mathbf{I}_{3N}$  with  $2 = \frac{2}{m} \tau$

It can be seen from Table I that the Ricci-Ciccotti algorithm also outperforms the biased random walk (12), as far as sampling issues are concerned. In the following, we shall therefore use the Ricci-Ciccotti algorithm.

### 3. Metropolized Langevin dynamics

The discretized Langevin dynamics does not exactly sample the target distribution  $\rho$ , but rather from some approximation  $\rho_\tau$  of  $\rho$ . It is therefore tempting to introduce a Metropolis acceptance/rejection step to further improve the quality of the sampling. Unfortunately, this idea cannot be straightforwardly implemented for two reasons:

first, this is not technically feasible, for the Markov chain defined by (9) does not have a transition density. Indeed, as the same Gaussian random vectors  $\mathbf{G}^n$  are used to update both the positions and the momenta, the measure  $\rho(\mathbf{R}^n; \mathbf{P}^n; \tau)$  is supported on a  $3N$ -dimensional submanifold of the phase space  $\mathbb{R}^{3N} \times \mathbb{R}^{3N}$ ;

second, leaving apart the above mentioned technical difficulty, which is specific to the Ricci-Ciccotti scheme, the Langevin dynamics is *a priori* not an efficient Markov chain for the Metropolis algorithm, for it does not satisfy the detailed balance property.

Let us now explain how to tackle these two issues, starting with the first one.

To make it compatible with the Metropolis framework, one needs to slightly modify the Ricci-Ciccotti algorithm. Following [2, 16], we thus introduce i.i.d. *correlated* Gaussian

vectors  $(G_{1,i}^n; G_{2,i}^n)$  ( $1 \leq i \leq 3N$ ) such that:

$$h(G_{1,i}^n)^2 i = \frac{2}{1} = \frac{t}{m} \left[ 2 - \frac{3}{4} \frac{e^{-t} + e^{-2t}}{t} \right]; \quad (20a)$$

$$h(G_{2,i}^n)^2 i = \frac{2}{2} = \frac{m}{1} \left[ 1 - e^{-2t} \right]; \quad (20b)$$

$$\frac{hG_{1,i}^n G_{2,i}^n i}{1 \cdot 2} = c_{12} = \frac{(1 - e^{-t})^2}{1 \cdot 2}; \quad (20c)$$

Setting  $G_1^n = (G_{1,i}^n)_{1 \leq i \leq 3N}$  and  $G_2^n = (G_{2,i}^n)_{1 \leq i \leq 3N}$ , the modified Ricci-Ciccotti algorithm reads

$$\begin{aligned} & \mathcal{R}^{n+1} = \mathcal{R}^n + \frac{t}{m} \mathcal{P}^n e^{-t/2} - \frac{t^2}{2m} r V(\mathcal{R}^n) e^{-t/4} + G_1^n; \\ & \mathcal{P}^{n+1} = \mathcal{P}^n e^{-t} + \frac{t}{2} r V(\mathcal{R}^n) + r V(\mathcal{R}^{n+1}) e^{-t/2} + G_2^n; \end{aligned} \quad (21)$$

The above scheme is a consistent discretization of (14) and the corresponding Markov chain does have a transition density, which reads (see Appendix)

$$\begin{aligned} T_t^{\text{MRC}}(\mathcal{R}^n; \mathcal{P}^n) \# (\mathcal{R}^{n+1}; \mathcal{P}^{n+1}) = \\ Z^{-1} \exp \left[ \frac{1}{2(1 - \frac{t}{2})} \left( \frac{j_1}{1} \right)^2 + \frac{j_2}{2} \right] 2 \mathcal{G}_2 \frac{d_1}{1} \frac{d_2}{2}; \end{aligned} \quad (22a)$$

with

$$d_1 = \mathcal{R}^{n+1} - \mathcal{R}^n - \frac{t}{m} \mathcal{P}^n e^{-t/2} + \frac{t^2}{2m} r V(\mathcal{R}^n) e^{-t/4}; \quad (22b)$$

$$d_2 = \mathcal{P}^{n+1} - \mathcal{P}^n e^{-t} + \frac{1}{2} t r V(\mathcal{R}^n) + r V(\mathcal{R}^{n+1}) e^{-t/2}; \quad (22c)$$

Unfortunately, inserting directly the transition density (22) in the Metropolis algorithm leads to a high rejection rate. Indeed, if  $(\mathcal{R}^n; \mathcal{P}^n)$  and  $(\mathcal{R}^{n+1}; \mathcal{P}^{n+1})$  are related through (21),  $T_t^{\text{MRC}}(\mathcal{R}^n; \mathcal{P}^n) \# (\mathcal{R}^{n+1}; \mathcal{P}^{n+1})$  usually is much greater than  $T_t^{\text{MRC}}(\mathcal{R}^{n+1}; \mathcal{P}^{n+1}) \# (\mathcal{R}^n; \mathcal{P}^n)$ , since the probability that the random forces are strong enough to make the particle go back in one step from where it comes, is very low in general. This is related to the fact that the Langevin dynamics does not satisfy the detailed balance relation.

It is however possible to further modify the overall algorithm by ensuring some microscopic reversibility, in order to finally obtain low rejection rates. For this purpose, we introduce momentum reversions. Denoting by  $T_t^{\text{Langevin}}$  the transition density of the Markov chain obtained by integrating (14) *exactly* on the time interval  $[t; t + \tau]$ , it is indeed not difficult to check (under convenient assumptions on  $V = \log j$ ), that the Markov chain defined by the transition density

$$\mathbb{P}_t^{\text{Langevin}}(\mathbb{R}; \mathbb{P}) ! (\mathbb{R}^0; \mathbb{P}^0) = T_t^{\text{Langevin}}(\mathbb{R}; \mathbb{P}) ! (\mathbb{R}^0; \mathbb{P}^0) \quad (23)$$

is ergodic with respect to  $\mathbb{P}$  and satisfies the detailed balance property

$$(\mathbb{R}; \mathbb{P}) \mathbb{P}_t^{\text{Langevin}}(\mathbb{R}; \mathbb{P}) ! (\mathbb{R}^0; \mathbb{P}^0) = (\mathbb{R}^0; \mathbb{P}^0) \mathbb{P}_t^{\text{Langevin}}(\mathbb{R}^0; \mathbb{P}^0) ! (\mathbb{R}; \mathbb{P}) : \quad (24)$$

Replacing the exact transition density  $T_t^{\text{Langevin}}$  by the approximation  $T_t^{\text{MRC}}$ , we now consider the transition density

$$\mathbb{P}_t^{\text{MRC}}(\mathbb{R}; \mathbb{P}) ! (\mathbb{R}^0; \mathbb{P}^0)^{\text{MRC}} = T_t^{\text{MRC}}(\mathbb{R}; \mathbb{P}) ! (\mathbb{R}^0; \mathbb{P}^0) : \quad (25)$$

The new sampling algorithm that we propose can be stated as follows:

Propose a move from  $(\mathbb{R}^n; \mathbb{P}^n)$  to  $(\mathbb{R}^{n+1}; \mathbb{P}^{n+1})$  using the transition density  $\mathbb{P}_t^{\text{MRC}}$ . In other words, perform one step of the modified Ricci-Ciccotti algorithm

$$\begin{aligned} & \begin{cases} \mathbb{R}^{n+1} = \mathbb{R}^n + \frac{t}{m} \mathbb{P}^n e^{-\frac{t}{2m} r V(\mathbb{R}^n)} e^{-\frac{t}{2m} r V(\mathbb{R}^{n+1})} e^{-\frac{t}{2m} G_1^n} \\ \mathbb{P}^{n+1} = \mathbb{P}^n e^{-\frac{t}{2} r V(\mathbb{R}^n) + r V(\mathbb{R}^{n+1})} e^{-\frac{t}{2} G_2^n} \end{cases} \end{aligned} \quad (26)$$

and set  $(\mathbb{R}^{n+1}; \mathbb{P}^{n+1}) = (\mathbb{R}^{n+1}; \mathbb{P}^{n+1})$

Compute the acceptance rate

$$\begin{aligned} & A((\mathbb{R}^n; \mathbb{P}^n) ! (\mathbb{R}^{n+1}; \mathbb{P}^{n+1})) \\ & = \min \left\{ \frac{(\mathbb{R}^{n+1}; \mathbb{P}^{n+1}) \mathbb{P}_t^{\text{MRC}}((\mathbb{R}^{n+1}; \mathbb{P}^{n+1}) ! (\mathbb{R}^n; \mathbb{P}^n))}{(\mathbb{R}^n; \mathbb{P}^n) \mathbb{P}_t^{\text{MRC}}((\mathbb{R}^n; \mathbb{P}^n) ! (\mathbb{R}^{n+1}; \mathbb{P}^{n+1}))}, 1 \right\} \end{aligned}$$

Draw a random variable  $\mathbb{U}$  uniformly distributed in  $(0;1)$  and

- if  $\mathbb{U}^n \leq A((\mathbb{R}^n; \mathbb{P}^n) ! (\mathbb{R}^{n+1}; \mathbb{P}^{n+1}))$ , accept the proposal:  $(\overline{\mathbb{R}}^{n+1}; \overline{\mathbb{P}}^{n+1}) = (\mathbb{R}^{n+1}; \mathbb{P}^{n+1})$ ,
- if  $\mathbb{U}^n > A((\mathbb{R}^n; \mathbb{P}^n) ! (\mathbb{R}^{n+1}; \mathbb{P}^{n+1}))$ , reject the proposal, and set  $(\overline{\mathbb{R}}^{n+1}; \overline{\mathbb{P}}^{n+1}) = (\mathbb{R}^n; \mathbb{P}^n)$ .

Reverse the momenta

$$(\mathbb{R}^{n+1}; \mathbb{P}^{n+1}) = (\overline{\mathbb{R}}^{n+1}; \overline{\mathbb{P}}^{n+1}) \quad (27)$$

Note that a momentum reversion is systematically performed just after the Metropolis step. As the invariant measure is left unchanged by this operation, the global algorithm (Metropolis step based on the transition density  $\mathbb{P}_t^{\text{MRC}}$  plus momentum reversion) actually samples  $\rho$ . The role of the final momentum reversion is to preserve the underlying Langevin dynamics: while the proposals are accepted, the above algorithm generates Langevin trajectories, that are known to efficiently sample an approximation of the target density  $\rho$ . Numerical tests seem to show that, in addition, the momentum reversion also plays a role when the proposal is rejected: it seems to increase the acceptance rate of the next step, preventing the walkers from being trapped in the vicinity of the nodal surface  $\psi^1(0)$ .

As the points  $(\mathbb{R}^n; \mathbb{P}^n)$  of the phase space generated by the above algorithm form a sampling of  $\rho$ , the positions  $(\mathbb{R}^n)$  sample  $\int_{\mathbb{R}^{3N}} \rho(\mathbf{r}) \mathbf{r}^j$  and can therefore be used for VMC calculations.

### III. NUMERICAL EXPERIMENTS AND APPLICATIONS

#### A. Measuring the efficiency

A major drawback of samplers based on Markov processes is that they generate sequentially correlated data. The effective number of independent observations is in fact  $L_{\text{eff}} = L/N_{\text{corr}}$ , where  $N_{\text{corr}}$  is the *correlation length*, namely the number of successive correlated moves.

In the following applications, we provide estimators for the correlation length  $N_{\text{corr}}$  and for the so-called inefficiency (see below), which are relevant indicators of the quality of the sampling. In this section, following Stedman *et al.* [12], we describe the way these quantities are defined and computed.

The sequence of samples is split into  $N_B$  blocks of  $L_B$  steps, where the number  $L_B$  is chosen such that it is a few orders of magnitude higher than  $N_{\text{corr}}$ . The empirical mean of the local energy reads

$$\langle E_L \rangle_{\mathbf{r}^j}^{N_B, L_B} = \frac{1}{N_B L_B} \sum_{i=1}^{N_B L_B} E_L(\mathbf{R}^i) \quad (28)$$

The empirical variance over all the individual steps is given by

$$\left[ \frac{1}{N_B L_B} \sum_{i=1}^{N_B L_B} E_L(R^i) - \langle E_L \rangle \right]^2 \quad (29)$$

and the empirical variance over the blocks by

$$\left[ \frac{1}{N_B} \sum_{i=1}^{N_B} E_{B,i} - \langle E_L \rangle \right]^2; \quad (30)$$

where  $E_{B,i}$  is the average energy over block  $i$ :

$$E_{B,i} = \frac{1}{L_B} \sum_{j=(i-1)L_B+1}^{iL_B} E_L(R^j); \quad (31)$$

Following [12], we define the correlation length as

$$N_{\text{corr}} = \lim_{N_B \rightarrow \infty} \lim_{L_B \rightarrow \infty} L_B \frac{\left[ \frac{1}{N_B L_B} \sum_{i=1}^{N_B L_B} E_L(R^i) - \langle E_L \rangle \right]^2}{\left[ \frac{1}{N_B} \sum_{i=1}^{N_B} E_{B,i} - \langle E_L \rangle \right]^2}; \quad (32)$$

and the inefficiency of the run as:

$$= \lim_{N_B \rightarrow \infty} \lim_{L_B \rightarrow \infty} L_B \left[ \frac{1}{N_B L_B} \sum_{i=1}^{N_B L_B} E_L(R^i) - \langle E_L \rangle \right]^2; \quad (33)$$

On the numerical examples presented below, the relative fluctuations of the quantities  $\frac{1}{L_B} \frac{\left[ \frac{1}{N_B L_B} \sum_{i=1}^{N_B L_B} E_L(R^i) - \langle E_L \rangle \right]^2}{\left[ \frac{1}{N_B} \sum_{i=1}^{N_B} E_{B,i} - \langle E_L \rangle \right]^2}$  and  $L_B \left[ \frac{1}{N_B} \sum_{i=1}^{N_B} E_{B,i} - \langle E_L \rangle \right]^2$  become small for  $L_B > 50$  and  $N_B > 50$ .

The definition of these two quantities can be understood as follows. Since  $L_B = N_{\text{corr}}$  and only  $L_B = N_{\text{corr}}$  are independent samples among the samples in the block, the central limit theorem yields  $E_{B,i} = \langle E_L \rangle + \frac{G^i}{\sqrt{L_B = N_{\text{corr}}}}$  where  $G^i$  are i.i.d. normal random variables. Thus, in the limit  $N_B \rightarrow \infty$  and  $L_B \rightarrow \infty$ , we obtain that  $\frac{1}{L_B} \left[ \frac{1}{N_B} \sum_{i=1}^{N_B} E_{B,i} - \langle E_L \rangle \right]^2 = \frac{1}{L_B = N_{\text{corr}}}$  which yields (32). The inefficiency is thus equal to  $N_{\text{corr}}^2$  and is large if the variance is large, or if the number of correlated steps is large.

Using this measure of efficiency, we can now compare the sampling algorithms (the simple random walk, the biased random walk and the Langevin algorithm) for various systems. In any case, a Metropolis acceptance/rejection step is used. We found empirically from several tests that convenient values for the parameters of the Langevin algorithm are  $\alpha = 1$  and  $m = Z^{3/2}$  where  $Z$  is the highest nuclear charge among all the nuclei. For each algorithm, we compare the efficiency for various values of the step length, namely the increment  $\Delta R$  in the case of the simple random walk, and the time-step  $\Delta t$  for the other two schemes. For

a given algorithm, simple arguments corroborated by numerical tests show that there exists an optimal value of this increment: for smaller (resp. for larger increments), the correlation between two successive positions increases since the displacement of the particle is small (resp. since many moves are rejected), and this increases the number of correlated steps  $N_{\text{corr}}$ .

One can notice on the results (see tables II, III, IV, V) that a large error bar corresponds to large values for  $N_{\text{corr}}$  and  $\epsilon$ . The quantities  $N_{\text{corr}}$  and  $\epsilon$  are a way to refine the measure of efficiency, since the same length of error bar may be obtained for different values of the numerical parameters.

Let us now present some numerical tests. We compare the algorithms and parameters at a fixed computational cost. The reference values are obtained by ten times longer VMC simulations. The error bars given in parenthesis are 60% confidence intervals. We also provide the acceptance rate (denoted by  $A$  in the tables) and, when it is relevant, the mean of the length of the increment  $\langle R^{n+1} - R^n \rangle$  over one time-step (denoted by  $\langle \Delta R \rangle$  in the tables) for the biased random walk and the Langevin dynamics.

## B. Atoms

*Lithium.* The Lithium atom was chosen as a first simple example. The wave function is the same as for the benchmark system used for the comparison of the various Langevin schemes, namely a single Slater determinant of Slater-type basis functions improved by a Jastrow factor to take account of the electron correlation. The reference energy associated with this wave function is  $-7.47198(4)$  a.u., and the comparison of the algorithms is given in table II. The runs were made of 100 random walks composed of 50 blocks of 1000 steps. For the simple random walk, the lowest values of the correlation length and of the inefficiency are respectively 11.4 and 1.40. The biased random walk is much more efficient, since the optimal correlation length and inefficiency are more than twice smaller, i.e. 4.74 and 0.55. The proposed algorithm is even more efficient: the optimal correlation length is 3.75 and the optimal inefficiency is 0.44.

*Fluorine.* The Fluorine atom was chosen for its relatively “high” nuclear charge ( $Z = 9$ ), leading to a timescale separation of the core and valence electrons. The wave function is a Slater-determinant with Gaussian-type basis functions where the 1s orbital was substituted

by a Slater-type orbital, with a reference energy of  $-99.397(2)$  a.u. The runs were made of 100 random walks composed of 100 blocks of 100 steps. The results are given in table III. For the simple random walk, the lowest values of the correlation length and of the inefficiency are respectively 15.6 and 282. The biased random walk is again twice more efficient than the simple random walk, for which the optimal correlation length and inefficiency are 7.4 and 137. The Langevin algorithm is more efficient than the biased random walk: the optimal correlation length is 5.3 and the optimal inefficiency is 102.

*Copper.* We can go even further in the timescale separation and take the Copper atom ( $Z = 29$ ) as an example. The wave function is a Slater determinant with a basis of Slater-type atomic orbitals, improved by a Jastrow factor to take account of the electron correlation. The reference energy is  $-1639.2539(24)$ . The runs were made of 40 random walks composed of 500 blocks of 500 steps. From table IV, one can remark that the Langevin algorithm is again more efficient than the biased random walk, since the optimal correlation length and inefficiency are respectively 28.7 and 4027, whereas using the biased random walk, these values are 51.0 and 5953.

### C. The phenol molecule

The Phenol molecule was chosen to test the proposed algorithm because it contains three different types of atoms (H, C and O). The wave function here is a single Slater determinant with Gaussian-type basis functions. The core molecular orbitals of the Oxygen and Carbon atoms were substituted by the corresponding atomic 1s orbitals. The comparison of the biased random walk with the Langevin algorithm is given in table V. The optimal correlation length using the biased random walk is 10.17, whereas it is 8.23 with our Langevin algorithm. The optimal inefficiency is again lower with the Langevin algorithm (544) than with the biased random walk (653).

### D. Discussion of the results

We observe that on our numerical tests, the Langevin dynamics is always more efficient than the biased random walk. Indeed, we notice that:

The error bar (or  $N_{\text{corr}}$ , or  $\dots$ ) obtained with the Langevin dynamics for an optimal

set of numerical parameters is always smaller than the error bar obtained with other algorithms (for which we also optimize the numerical parameters).

The size of the error bar does not seem to be as sensitive to the choice of the numerical parameters as for other methods. In particular, we observe on our numerical tests that the value  $\tau = 0.2$  seems to be convenient to obtain good results with the Langevin dynamics, whatever the atom or molecule.

## APPENDIX A: DERIVATION OF THE TRANSITION PROBABILITY (22)

The random vector  $(\mathbf{d}_1; \mathbf{d}_2)$  (defined by (22b)–(22c)) is a Gaussian random vector and therefore admits a density with respect to the Lebesgue measure in  $\mathbb{R}^{6N}$ . If, for  $1 \leq i \leq 3N$ , we denote by  $d_{1,i}$  (resp.  $d_{2,i}$ ) the components of  $\mathbf{d}_1$  (resp.  $\mathbf{d}_2$ ), we observe that the Gaussian random vectors  $(\mathbf{d}_{1,i}; \mathbf{d}_{2,i})$  are i.i.d. Therefore, the transition probability  $T(\mathbb{R}^n; \mathbb{P}^n) : (\mathbb{R}^{n+1}; \mathbb{P}^{n+1})$  reads

$$T(\mathbb{R}^n; \mathbb{P}^n) : (\mathbb{R}^{n+1}; \mathbb{P}^{n+1}) = Z^{-1} (\mathfrak{p}(\mathbf{d}_{1,i}; \mathbf{d}_{2,i}))^{3N} \quad (\text{A1})$$

where  $Z$  is a normalization constant and  $\mathfrak{p}$  denotes the density (in  $\mathbb{R}^2$ ) of the Gaussian random vectors  $(\mathbf{d}_{1,i}; \mathbf{d}_{2,i})$ .

From equations (21), one can see that

$$\begin{aligned} \mathbf{d}_{1,i} &= \mathbf{R}_i^{n+1} - \mathbf{R}_i^n - \frac{\mathfrak{P}_i^n}{m} \mathbf{e}^{-\tau} + \frac{\tau^2}{2m} \mathbf{r}_i V(\mathbf{R}^n) \mathbf{e}^{-\tau}; \\ \mathbf{d}_{2,i} &= \mathbf{P}_i^{n+1} - \mathbf{P}_i^n \mathbf{e}^{-\tau} + \frac{1}{2} \tau \mathbf{r}_i V(\mathbf{R}^n) + \mathbf{r}_i V(\mathbf{R}^{n+1}) \mathbf{e}^{-\tau}; \end{aligned}$$

is a Gaussian random vector with covariance matrix  $\mathbf{C}_{12} = \begin{pmatrix} \frac{1}{2} & \frac{1}{2} \\ \frac{1}{2} & \frac{1}{2} \end{pmatrix}$ . Thus

$$\mathfrak{p}(\mathbf{d}_1; \mathbf{d}_2) = \frac{1}{2} \frac{1}{\det \mathbf{C}_{12}} \exp \left[ -\frac{1}{2} (\mathbf{d}_1; \mathbf{d}_2) \mathbf{C}_{12}^{-1} (\mathbf{d}_1; \mathbf{d}_2)^T \right] \quad (\text{A2})$$

## TABLE CAPTIONS

TableI: Comparison of different discretization schemes for Langevin dynamics. The reference energy is  $-7.47198(4)$  a.u.

TableII : The Lithium atom: Comparison of the Simple random walk, the Biased random walk and the proposed Langevin algorithm. The runs were carried out with 100 walkers, each realizing 50 blocks of 1000 steps. The reference energy is  $-7.47198(4)$  a.u.

TableIII : The Fluorine atom : Comparison of the Simple random walk, the Biased random walk and the proposed Langevin algorithm. The runs were carried out with 100 walkers, each realizing 100 blocks of 100 steps. The reference energy is  $-99.397(2)$  a.u.

TableIV : The Copper atom: Comparison of the Biased random walk with the proposed Langevin algorithm. The runs were carried out with 40 walkers, each realizing 500 blocks of 500 steps. The reference energy is  $-1639.2539(24)$  a.u.

TableV : The Phenol molecule : Comparison of the Biased random walk with the proposed Langevin algorithm. The runs were carried out with 100 walkers, each realizing 100 blocks of 100 steps. The reference energy is  $-305.647(2)$  a.u.
