(dated: December 17, 2021)

Starting from the t - J model, we derive an effective field theory describing the spin dynamics in the insulating phase of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$, $x \sim 0.055$, at low temperature. Using Monte Carlo simulations, we show that the destruction of Neel order is driven by the single-hole localization length ξ . A phase transition at 2% doping is consistent with the value of ξ known from the variable range hopping conductivity. The static spin structure factor obtained in our calculations is in perfect agreement with neutron scattering data over the whole range of doping. We also demonstrate that topological defects (spin vortex-antivortex pairs) are an intrinsic property of the spin-glass ground state.

Introduction. One of the most intriguing properties of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ (LSCO) is the static incommensurate magnetic ordering at low temperature observed in elastic neutron scattering experiments. This ordering manifests itself as a scattering peak shifted with respect to the antiferromagnetic position: $Q = Q_{AF} + Q$, where $Q_{AF} = (\pi/a; 0; 0)$, setting the lattice spacing $a = 1$ and using the tetragonal coordinate system. The incommensurate ordering is a generic feature of LSCO. According to experiments in the Neel phase, $x \sim 0.02$, the incommensurability is almost doping independent and directed along the orthorhombic b axis, $Q \sim 0.022(\pi/a; 0; 0)$, see Ref. 1. In the spin-glass phase ($0.02 < x < 0.055$), the shift is again directed along the orthorhombic b axis, but scales linearly with doping, $Q \sim 2x(\pi/a; 0; 0)$, see Refs. [2, 3, 4]. Finally, in the underdoped superconducting region ($0.055 < x < 0.12$), the shift scales linearly with doping and is directed along the crystal axes of the tetragonal lattice, $Q \sim 2x(\pi/a; 0; 0)$ or $Q \sim 2x(0; \pi/b; 0)$, see Ref. 5.

These observations caused a renewal of theoretical interest in the idea of spin spirals in cuprates, both, from the phenomenological [6, 7, 8, 9] and the microscopic [10, 11, 12] point of view. The jump of the spiral direction at the insulator-superconductor transition ($x \sim 0.055$) was explained in Ref. 11 and a mechanism for the pinning of the spiral direction to the orthorhombic b axis in the insulating phases (Neel and spin-glass regime) was suggested in Ref. 12. In this letter, we formulate an effective field theory that describes the spin-glass phase of LSCO at low temperature. We study the ground state, calculate the spin structure factor, and analyze the nature of the quantum phase transition from the Neel to the spin-glass state.

Model. In insulating LSCO, holes are trapped by Sr ions and form hydrogen-like bound states $\psi(r) = \langle r | \psi \rangle = \frac{1}{\sqrt{2\pi\xi^2}} e^{-r/\xi}$, where ξ is a two-component spinor describing the pseudospin [11] and 0.4 is the inverse localization length [13]. We refer to these bound states as impurities [14]. The temperature corresponding

to the binding energy is about $T_b \sim 100\text{K}$ [11]; hence at $T > T_b$ the charge degrees of freedom are frozen. Due to the small orthorhombic distortion of LSCO, impurities in the $S_b = (\pi/2; \pi/2)$ hole pocket have lower energy than impurities in the vicinity of $S_a = (\pi/2; -\pi/2)$. From the estimation of the pinning energy [12], we conclude that for $T < T_p \sim 30\text{K}$, impurities are pinned to the S_b valley and the spirals are directed along the b axis, as explained in Ref. 11. Since we consider $T < T_p$, the relevant degrees of freedom are the spins of the Cu ions and the impurity pseudospins.

It is convenient to describe the staggered component of the copper spins by a continuous vector field $\mathbf{n}(r)$ within the framework of the non-linear σ -model (NLSM). Throughout this letter, we use the usual bold font for vectors in coordinate space and denote vectors acting in spin space by arrows. We use the same orthorhombic coordinate system in both cases, i.e., $\mathbf{e} = \mathbf{e}$, see Fig. 1. Having in mind the above discussion of the relative degrees of freedom, we write the energy of a single layer of LSCO as

$$\begin{aligned} & \frac{1}{2} \int d^2r \left[J \mathbf{n}(r) \cdot \nabla^2 \mathbf{n}(r) + \frac{D^2}{2} [\mathbf{n}^a(r)]^2 + \frac{c}{2} [\mathbf{n}^c(r)]^2 \right] \\ & + \frac{1}{2g} \sum_i \int d^2r \left[\mathbf{n}(r) \cdot \mathbf{I}_i \cdot \mathbf{n}(r) + \mathbf{I}_i \cdot (\mathbf{e}_b - r) \mathbf{n}(r) \right]; \end{aligned} \quad (1)$$

where $\mathbf{n} = (n^a; n^b; n^c)$ denotes the components of the \mathbf{n} -eld, subject to the constraint $\mathbf{n}^2 = 1$. The first line in (1) is the elastic energy which takes into account the Dzyaloshinski-Moriya (DM) and the XY anisotropies, with $D \sim 2\text{ meV}$ and $\frac{D^2}{c} \sim 4\text{ meV}$. We use $J \sim 0.18\text{J}$ for the spin stiffness and $c \sim 1.66\text{J}$ for the spin-wave velocity, with $J \sim 130\text{ meV}$. These parameters follow from neutron scattering data at zero doping [15]. The second line in (1) represents the interaction of the \mathbf{n} -eld with the impurity pseudospins $\mathbf{I}_i = \frac{1}{2} \mathbf{\sigma}_i$, see Ref. 12. The impurities are located at positions \mathbf{r}_i and $\mathbf{r} = \mathbf{r}_i + \mathbf{r}$. The coupling constant $g \sim J$ has been calculated pre-

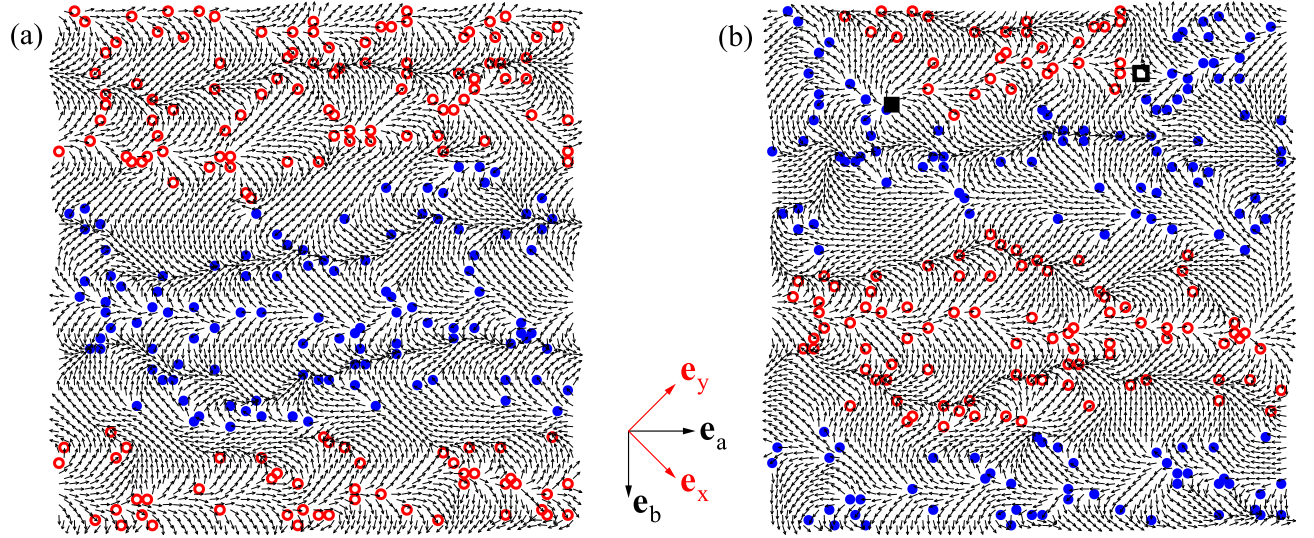

FIG. 1: (Color online). Characteristic ground state configuration of a particular realization at $x = 0.05$. The system (a) without defects has higher energy than the same system (b) with a vortex-antivortex pair (squares). The impurity pseudospins \mathbf{l}_i are oriented along the c axis. Full (open) circles correspond to values ± 1 (± 1). Small arrows represent the \mathbf{n} -eld. The system forms domains stretched along the a direction, in which all the pseudospins are aligned in parallel.

viously within the extended t - J model [10]. Eq. (1) describes the static limit of the effective eld theory. This limit is sufficient to study ground state properties because (1) results in a long-range interaction [see Eq. (5) below].

The anisotropies in Eq. (1) pin the \mathbf{n} -eld to a particular spatial direction. Because the XY term is larger than the DM anisotropy, $\frac{p_c}{c} > D$, the staggered eld \mathbf{n} is coplanar and lies in the ab plane. For a single CuO_2 layer at zero temperature, there is no mechanism that deflects \mathbf{n} out of this plane. Substituting $\mathbf{n} = n^a; n^b; n^c = (\sin \theta; \cos \theta; 0)$ in Eq. (1), the energy of the effective O (2) NLSM reads

$$\frac{s}{2} \int d^2r [\mathbf{r} \cdot \nabla \mathbf{n}(\mathbf{r})]^2 + 2M \sum_i \mathbf{l}_i \cdot \mathbf{n}(\mathbf{r}_i) (e_b \cdot \mathbf{r}_i) \cdot \mathbf{n}(\mathbf{r}); \quad (2)$$

where $\mathbf{l}_i = \frac{y}{p_c} \mathbf{p}_i$ is an Ising variable taking the values ± 1 and $M = \frac{c}{2g} \approx 8$. In (2) we have neglected the DM term $\frac{D^2}{c^2} \sin^2 \theta$. Despite its smallness, $D^2 = c^2 \approx 10^4$, this term is important in the Neel phase where it pins the \mathbf{n} -eld to the b axis, i.e., $\theta = 0$. However, in the spin-glass phase, the angle $\theta(\mathbf{r})$ quickly varies at a scale much shorter than $\lambda_M = c/D \approx 100$ and since $\hbar \sin^2 \theta = 1/2$, the DM term can be safely neglected. Very importantly, Eq. (2) is exact in the sense that it is valid for arbitrary and not restricted to small angles.

To integrate out the \mathbf{n} -eld, we start with a single impurity. The variation of Eq. (2) with respect to \mathbf{n} yields $\mathbf{r}^2 \cdot \nabla \mathbf{n}(\mathbf{r}) + M \mathbf{l} (e_b \cdot \mathbf{r}) \cdot \mathbf{n}(\mathbf{r}) = 0$, which has the solution

$$\mathbf{n}(\mathbf{r}) = \mathbf{l} \#(\mathbf{r}), \text{ where}$$

$$\#(\mathbf{r}) = \frac{M}{2} \frac{e_b \cdot \mathbf{r}}{r^2} (1 + 2 \mathbf{r} \cdot \mathbf{e}_b) e^{2 \mathbf{r} \cdot \mathbf{e}_b} \quad (3)$$

Because of the linearity of the problem, the solution for N impurities is the superposition

$$\mathbf{n}(\mathbf{r}) = \sum_{i=1}^N \mathbf{l}_i \#(\mathbf{r} - \mathbf{r}_i) \quad (4)$$

Substituting this solution into Eq. (2) yields an expression of the energy in terms of the Ising pseudospins \mathbf{l}_i only

$$E_I = \frac{sM^2}{2} \sum_{i \neq j} \mathbf{l}_i \mathbf{l}_j [F_1(r_{ij}) + \cos(2 \theta_{ij}) F_2(r_{ij})] g; \quad (5)$$

with $F_1(y) = y^2 K_2(2y)$ and $F_2(y) = 1 - y^2 K_3(2y)$. Here θ_{ij} is the angle between the vectors \mathbf{e}_b and $\mathbf{r}_{ij} = \mathbf{r}_i - \mathbf{r}_j$, and K_n are modified Bessel functions. For $r \rightarrow 1$, the above expression is equivalent to the usual dipole-dipole interaction $\propto \cos(2 \theta_{ij}) = r_{ij}^2$.

Ground state and destruction of Neel order. We perform classical Monte Carlo simulation to find the ground state of the Ising pseudospins described by Eq. (5) using the same algorithm as in Ref. 12. Because samples of LSCO consist of many CuO_2 layers with randomly distributed dopants, we average observables over many realizations of random impurity distributions. For a particular realization, we consider up to $N = 200$ Ising pseudospins \mathbf{l}_i on a square lattice of size $L = N^{1/2}$. In order to minimize finite-size effects, we orient the lattice

FIG. 2: (a) n^b as a function of doping x . For $\kappa = 0.4$, Neel order is destroyed at $x_c = 0.02$, in agreement with experiments. For pointlike impurities ($\kappa \rightarrow \infty$), there is no phase transition at least up to $x = 0.05$. (b) Neutron scattering probability S_q for $x = 0.04$. Full circles correspond to experimental observations taken from Fig. 4 in Ref. 4, with normalized intensities. The curve represents our simulation, containing no fitting parameters. (c) Incommensurability (in reciprocal lattice units of the tetragonal lattice) as a function of doping. Our calculations (circles) are in good agreement with experimental measurements (squares) taken from Ref. 1, 3, 18, see Fig. 6 of Ref. 1. Theoretical points for the Neel phase are taken from Ref. 12

along the orthorhombic coordinate system, apply periodic boundary conditions along the a axis and extract relevant quantities only from the central quarter of the system. The b direction is left open, in order not to impose an artificial constraint on the spiral pitch. Once the Ising ground state is found, the n -eld is determined according to Eq. (4). Note that ϕ in (4) can always be shifted by a constant ϕ_0 . We set $\phi_0 = 0$ and therefore have $\phi = 0$ and $n = \phi$ in the undoped system. Fig. 1(a) shows a characteristic spin-glass ground state for a particular realization at doping $x = 0.05$. Open (full) circles show the Ising pseudospins directed parallel (antiparallel) to the c axis (orthogonal to the plane). The n -eld is represented by arrows. The system forms large domains, stretched along the a axis, in which the pseudospins all point in the same direction. Fig. 1(a) nicely illustrates the concept of spiral formation. Despite the random distribution of impurities, one easily recognizes horizontal lines along which the n -eld remains almost constant. In contrast to a uniform spiral, these lines are not exactly parallel to the a axis, but meander around the impurities.

The presence of Neel order can be identified as a non-zero n^b . For a given doping, the average is taken over the central quarter of the system and over many realizations of random impurity positions. We first performed calculations for $\kappa \rightarrow \infty$ (pointlike impurities) and found that Neel order is not destroyed at least up to $x = 0.05$, see Fig. 2(a). In this case, the pseudospins align in an antiparallel pattern along the b direction, on a scale of the order of the separation between impurities. The angle is thus small and the resulting n -eld never completes a full rotation. For finite κ , the situation is qualitatively different because for sufficiently small distances between impurities, the combination in brackets following in Eq. (5)

is always negative. This favors parallel alignment of the pseudospins and hence leads to the formation of parallel Ising domains, see Fig. 1(a). The domains have a finite width because the long-range tail of (5) still favors antiparallel alignment along the b direction. The width w depends on doping x and on κ , but also on the size of the lattice as $w \propto L$. The domains thus become macroscopic in the thermodynamic limit. The mechanism for the domain formation is exactly the same as for ferromagnets [16]. We will show in the following paragraph that topological defects lead to finite, but still very large domain sizes. The doping dependence of n^b for $\kappa = 0.4$ is shown in Fig. 2(a). The phase transition takes place at $x_c = 0.02$, in very good agreement with experiments. The small deviations from zero at $x = 0.02$ in Fig. 2(a) are due to finite size effects. It is remarkable that the correct critical concentration x_c is obtained for $\kappa = 0.4$ that is known from the variable range hopping conductivity [13].

Topological defects. There are two kinds of topological defects in a 2D O(3) NLSM, vortices and instantons [17]. Instantons lead to non-coplanar spin configurations that, according to our calculations, increase the energy because the system prefers coplanar pseudospin arrangements. Instantons are therefore not present in the ground state. For vortices, the situation is different. Let us consider solutions of the Laplace equation $\nabla^2 r^2 = 0$ of the form $\phi(r) = \sum_{j=1}^M Q_j \arg [x - X_j + i(y - Y_j)]$. Here $R_j = (X_j, Y_j)$ and $Q_j \in \mathbb{Z}$ are the positions of the impurities and their topological charges (winding numbers), respectively. The energy is minimal for vanishing total topological charge with $\sum Q_j = 0$. In this case, we have $M=2$ pairs of vortices with opposite winding numbers. For large average separation between vortices,

$R = 1$, the associated energy calculated with logarithmic accuracy is [17]

$$E_V = M_s \ln R : \quad (6)$$

Because this energy is positive, vortices never appear in the ground state of the NLSM without impurities. However, in a doped system, one also has to take into account the interaction energy E_{IV} between impurities and vortices. From Eq. (2), we find

$$E_{IV} = \sum_{i,j=1}^{N_M} \frac{1}{L^2} \frac{e_a}{2} \frac{ij}{ij} \left(1 - e^{2ij} (1 + 2ij) \right) ; \quad (7)$$

where $ij = (R_j - r_i)$ are the positions of the vortices with respect to the impurities. The interaction energy (7) is large and negative because of the domains formed in the spin-glass phase, in which all pseudospins point in the same direction. It therefore favors the creation of vortices at zero temperature. The total energy is now given by the sum of (5), (6) and (7). An illustration of a system with one vortex-antivortex pair is shown in Fig. 1(b). Compared to the same realization without defects [Fig. 1(a)], the energy is around 10% lower. The presence of vortices renders the problem of finding the ground state quite difficult. In addition to minimizing the energy of the Ising pseudospins, one also has to check if vortex-antivortex pairs can lower the energy, and if so, optimize their positions. Nevertheless, it is possible to estimate the optimal distance between defects in the thermodynamic limit. Because of the long-range nature of the interaction (7), the energy gain is proportional to R . Let us denote the energy of the system without vortices by $E = E_I$ and use $\tilde{E} = E_I + E_{IV} + E_V$ for a system with M defects. The energy gain due to vortices can then be expressed as $E = \tilde{E} - E = xM R + M_s \ln R$. By comparing the energies of systems with 4 and 16 vortices to the same realizations without defects, we find that this formula gives the correct R dependence. The parameter x is weakly doping dependent, at $x = 0.02$, we obtain $x = 2.0$, leading to an optimal distance $R_{opt} = 130$ in the thermodynamic limit. At $x = 0.05$, we find $x = 1.1$ from which we deduce $R_{opt} = 90$. We thus conclude that vortex-antivortex pairs break up the domains and lead to a parquet-like arrangement of Ising pseudospins with a natural domain size $R = 100$.

Static spin structure factor and neutron scattering. Let us finally calculate the structure factor

$$S_q = \frac{1}{L^2} \sum_{ij} e^{iq \cdot (r_i - r_j)} n(r_i) n(r_j) ; \quad (8)$$

as well as the sum $S_q = \sum_i S_q$, which is related to the neutron scattering cross section. Fig. 2(b) shows experimental data taken by Fujita et al. [4] on a sample with doping $x = 0.04$ together with our theoretical results for

S_q . The agreement between theory and experiment is quite remarkable, especially given the fact that it is not restricted to a particular sample, but can be observed over a broad range of doping. This latter finding is illustrated in Fig. 2(c), which shows the incommensurability δ , defined as half the distance between the peaks, as a function of doping. Expressed in reciprocal lattice units of the tetragonal structure, the incommensurability is in good approximation proportional to doping, $\delta = x$. Because of their low density, topological defects do not have a major influence on S_q , and only lead to some broadening of the peaks.

To conclude, we have developed a low energy effective field theory that describes the magnetic structure of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ in the spin-glass phase ($x = 0.055$). We have shown that the staggered component of the copper spins is confined to the ab plane, due to the XY anisotropy. The static spin structure factors obtained in our approach are in excellent agreement with neutron scattering data, over a whole range of doping. We have analyzed the nature of the quantum phase transition from the Neel to the spin-glass phase and have also shown that topological defects (spin vortices) play a significant role in the ground state of the spin-glass phase.

We would like to thank A.N. Lavrov for valuable discussions. A.I.M. gratefully acknowledges the School of Physics at the University of New South Wales for warm hospitality and financial support during his visit. The Monte Carlo simulations have been performed on computers belonging to the Institut Romand de Recherche Numérique en Physique des Matériaux (IRRM) in Switzerland.
