Abstract. – We introduce a new type of Gutzwiller variational wavefunction for correlated electrons coupled to phonons, able to treat on equal footing electronic and lattice degrees of freedom. We benchmark the wavefunction in the infinite-U Hubbard-Holstein model away from half-filling on a Bethe lattice, where we can directly compare with exact results by Dynamical Mean-Field Theory. For this model, we find that variational results agree perfectly well with the exact ones. In particular the wavefunction correctly describes the crossover to a heavy polaron gas upon increasing the electron-phonon coupling.

The coherent electron motion is strongly slowed down by Coulomb repulsion close to a Mott metal-to-insulator transition. In this situation the effects of the electron-lattice coupling may be enhanced, since the lattice has more time to adjust following the electron motion. In fact, the Mott transition in real systems is often accompanied by substantial structural changes that turn it into a strong first-order one, as it happens in the prototypical example of V_2O_3 . [1] However, despite its relevance in many strongly correlated materials, the electron-phonon (e-ph) interaction has been just touched on in the context of the Mott transition. This has happened partly because most theoretical efforts have focused mainly on the strong correlation alone, or on the purely e-ph driven polaron problem, but also because it is not obvious how to deal with the e-ph coupling once the electron-electron repulsion slackens quasiparticle motion so much that the phonon dynamics becomes comparable or even faster. For this reason, recent attempts to understand the role of the e-ph coupling near a Mott transition have mainly limited to "exact" numerical simulations using several techniques, including Quantum Monte Carlo [2,5], exact diagonalization [6], Density-Matrix Renormalization Group [7] and Dynamical Mean-Field Theory (DMFT) [8,9] or extensions [10]. However, besides accurate numerical results,

it is desirable to have at disposal also analytic or semi-analytic approaches, even though approximate, that may provide us with simple and intuitive physical insights and may be extended to situations where numerical approaches become hardly feasible.

A popular and simple tool for the study of strongly correlated electron systems, so far in the absence of e-ph interaction, is the Gutzwiller variational approach. In its simplest version [11], the Gutzwiller approach amounts to variationally modify the relative weights of the local electronic configurations of an uncorrelated wavefunction. This variational wavefunction is able to describe a Mott transition only in the limit of infinite coordination [12], where the expectation value of the Hamiltonian can be calculated analytically. In finite-coordination lattices, it has been recently argued [13] that the Gutzwiller wavefunction may still describe a Mott transition once a long-range Jastrow factor is included. In this paper we propose an extension of the Gutzwiller wavefunction to account for the e-ph coupling, which we label Gutzwiller Phonon Wavefunction (GPW). We test the accuracy of this wavefunction in the Hubbard-Holstein model on a Bethe lattice, where analytical results can be obtained and compared with "exact" DMFT calculations.

We consider an Hubbard-Holstein model

$$H = \sum_{\langle ij \rangle} t_{ij} c_i^\dagger c_j + U \sum_i n_i n_{i\#} + \sum_i \omega_0 b_i^\dagger b_i + \sum_i \lambda_0 (n_i - 1) (b_i^\dagger + b_i) \quad (1)$$

where c_i (c_i^\dagger) and b_i (b_i^\dagger) are annihilation (creation) operators at site i for spinless electrons and for dispersionless phonons of frequency ω_0 , respectively, U the on-site Hubbard repulsion while λ_0 parameterizes the e-ph coupling. The hopping $t = \frac{p}{z}$ connects nearest neighbor sites on a Cayley tree with coordination number z . The calculations will actually be performed in the limit $z \rightarrow 1$, namely for the so-called Bethe lattice, which has a semi-circular density of states with halfbandwidth $D = 2t$. The e-ph properties are conveniently parameterized through the adiabaticity parameter $\lambda = \lambda_0 \omega_0 = D$, and the dimensionless coupling $\tilde{\lambda} = 2 \lambda_0 \omega_0 = 2 \tilde{\lambda}$. The choice of a Bethe lattice has the advantage to allow for analytical calculations which can be compared directly with DMFT, which is exact in infinite-coordination lattices. In the DMFT calculations we use exact diagonalization as impurity solver, with the conduction bath approximated by a finite number of levels $N_b = 9$. We refer to Refs. [9] for more details on the practical implementation of this technique to the Hubbard-Holstein model. The phase diagram of the Hamiltonian (1) contains several different phases depending on the various parameters $\tilde{\lambda}$, λ , $U=D$ as well as on the electron density. In order to simplify the analysis, we will assume a very large, actually infinite, $U=D$, which excludes superconductivity. Moreover we will discard the possible occurrence of ferrromagnetism very close to half-filling. Under these assumptions, we expect, away from half-filling, an evolution from a strongly correlated metal at small $\tilde{\lambda}$ into a gas of heavy polarons at large $\tilde{\lambda}$. Previous DMFT calculations [9] have shown that this evolution is continuous for large (but finite) U , although the crossover may be quite sharp, while variational Lang-Firsov transformations within the slave-boson approach [14] find instead a first order phase transition between the two metallic phases [15]. We show that polaron formation occurs as a crossover also for $U=D \rightarrow 1$, and that our novel variational approach agrees extremely well, also quantitatively with exact DMFT, correctly describing the crossover.

In analogy with purely electronic models [16,17], we introduce a Gutzwiller wavefunction that depends also on the phonon coordinates $x_i = (b_i + b_i^\dagger) = \frac{p}{2}$ through:

$$|j\rangle_i = \sum_i P_i(x_i) |j\rangle_{0i}; \quad (2)$$

where $|j\rangle_{0i}$ is an uncorrelated fermionic wavefunction, here assumed to be the non interacting Fermi sea. The Gutzwiller correlator is defined by

$$P_i(x_i) = \sum_{\alpha=0,1,2} \frac{s}{P^{(\alpha)}} (x_i)^{\tilde{j}; i}; \tilde{j} \quad (3)$$

where $\tilde{j}; i$; i ; j is the projection operator at site i onto the subspace with electron number $\alpha = 0;1;2$, P are variational parameters while $P^{(\alpha)}$ are the occupation probabilities of the Fermi sea, i.e., $P_0^{(\alpha)} = (1 - n=2)^\alpha$, $P_1^{(\alpha)} = n(1 - n=2)$, and $P_2^{(\alpha)} = (n=2)^\alpha$, n being the average number of electrons per site. Finally, (x_i) are normalized functions associated to the different local electronic configurations. The introduction of this variational freedom is the novelty of our approach. We emphasize that the wavefunction (2) can be easily modified to account for other types of e-ph coupling as well as for the phonon dispersion, although that would likely require numerical evaluation of the energy and optimization of the variational parameters. For instance, phonon dispersion can be included if $|j\rangle_{0i} = (x_1; x_2; \dots; x_N) |j\rangle_{0i}$, where $(x_1; x_2; \dots; x_N)$ is a variational many-body phonon wavefunction that includes inter-site correlations.

Without loss of variational freedom, we can impose that $\int dx_i h_0(x) |j\rangle_{0i} = 1$ and $\int dx_i h_0(x) n_i P_i^2 |j\rangle_{0i} = n$. These two constraints are fulfilled by $P_0 = d + \frac{p}{2}$, $P_1 = 1 - 2d$, and $P_2 = d - 2$, having introduced the parameter $d = (P_0 + P_2)/2$ and the deviation from half-filling $\delta = 1 - n$. The variational approach amounts to compute the expectation value of the Hamiltonian (1) over the state (2). In infinite-coordination lattices such as our Bethe lattice the computation becomes straightforward thanks to the parameterization in eq. (3) [16,17], and leads to a variational energy per site

$$E = \sum_{\alpha=0,1,2} P_\alpha h_\alpha(x) + \frac{p}{2} \omega_0 P_0 h_0(x) + \sum_i P_2 h_2(x) + \frac{2\tilde{j}}{1} \tilde{j} + U P_2; \quad (4)$$

Here $h_\alpha(x) = \int dx (x^2 + x^2)$, $h_{\alpha\alpha}$ indicates the average over (x) , \tilde{j} is the Fermi sea average of the hopping energy per site. The hopping renormalization, S , is proportional to the overlap between the phonon wavefunctions corresponding to two different electronic configurations according to

$$S = \sum_{\alpha=0,1} \frac{p}{P P_{\alpha+1}} \int dx (x)_{\alpha+1}(x); \quad (5)$$

Minimization with respect to d leads to

$$U + h_0(x)_{00} + h_0(x)_{02} - 2h_0(x)_{01} + \frac{p}{2} \omega_0 h_0(x)_{00} - h_0(x)_{02} - \frac{2\tilde{j}}{1} \frac{\partial \tilde{j}}{\partial d} = 0; \quad (6)$$

while that with respect to the phonon wavefunctions yields the following non-linear second-order differential equations

$$\frac{0}{P_0} \omega_0 = h_0(x)_{00} + \frac{p}{2} \omega_0 x_{00} - \frac{2\tilde{j}}{1} S \frac{q}{P_0} \frac{1}{1}; \quad (7)$$

$$\frac{1}{P_1} \omega_1 = h_0(x)_{01} - \frac{2\tilde{j}}{1} S \frac{q}{P_1} \omega_0 + S \frac{q}{P_1} \frac{2}{2}; \quad (8)$$

$$\frac{2}{P_2} \omega_2 = h_0(x)_{02} - \frac{p}{2} \omega_0 x_{02} - \frac{2\tilde{j}}{1} S \frac{q}{P_2} \frac{1}{1}; \quad (9)$$

where the λ 's are Lagrange multipliers introduced to enforce the normalization conditions of each $\psi(\mathbf{x})$. These equations describe a system of forced harmonic oscillators coupled together by a term proportional to $\mathbf{j}^T \mathbf{j}$. The latter can be neglected in the antiadiabatic regime $\lambda \gg \mathbf{j}^T \mathbf{j}$ so that the wavefunctions ψ 's are just displaced oscillators whose displacement is associated to the different local electronic configurations. In the opposite adiabatic regime $\lambda \ll \mathbf{j}^T \mathbf{j}$, the coupling term is instead dominant. This introduces a tight entanglement between the different phonon-wavefunctions and strong anharmonicity.

As we mentioned we consider here the $U \rightarrow 1$ limit, where double occupation is not allowed, hence $P_2 = 0$ and $P_0 = \frac{1}{2}$, $P_1 = \frac{1}{2}$, leaving us with the two coupled equations (7) and (8) for ψ_0 and ψ_1 . We solve them iteratively by expanding the phonon wavefunctions in eigenstates of h_0 , ψ_i , with energy ϵ_i as $\psi_0 = \sum c_n \psi_i$ and $\psi_1 = \sum d_n \psi_i$. The equations for the coefficients c_n and d_n are

$$\frac{1}{P_0} \sum_n \epsilon_n c_n + \frac{P_1}{2} \sum_n \epsilon_n d_n + \frac{2\mathbf{j}^T \mathbf{j}}{1} P_1 d_n c_n = 0;$$

$$\frac{1}{P_1} \sum_n \epsilon_n d_n + \frac{2\mathbf{j}^T \mathbf{j}}{1} P_0 c_n d_n = 0$$

In practice $n \sim 100$ is sufficient to get accurate values for the ground state corresponding to the lowest ψ_0 and ψ_1 .

A key quantity that characterizes the electronic properties is the effective mass m^* , obtained through $m^* = \frac{1}{\partial \epsilon(\mathbf{k}) / \partial \mathbf{k}}$, being $\epsilon(\mathbf{k})$ the single-particle self-energy which, for infinite coordination, is momentum independent. Within the Gutzwiller approach, the effective mass is commonly identified as the hopping renormalization factor, which, through eq.(5), is given by

$$m^*(\lambda) = m(0) \frac{1}{\langle \psi_0 | \psi_0 \rangle}; \quad (10)$$

where the overlap $\langle \psi_0 | \psi_0 \rangle$ includes the effect of phonons, while $m(0)$ only the correlation effects.

Fig. 1: (Color online) Effective mass as a function of λ and for different values of δ at $t = 0.2$.

Fig. 2: (Color online) $m^*(\lambda) = m^*(0)$ as a function of λ at $t = 1.5$ and $\delta = 0.3$ in DMFT (squares) and GPW (circles).

In Fig. 1 we draw $m^*(\lambda) = m^*(0)$, eq. (10), for different dopings as function of λ for $t = 0.2$, in the adiabatic range. The logarithmic scale on the vertical axis is used to show how the method reliably works for arbitrary value of the coupling. The linear scale in the inset emphasizes the onset of polaronic behavior, identified by a rapid growth of m^* . As we anticipated, in our calculation the formation of polarons occurs via a crossover, in agreement with DMFT calculations. Approaching half-filling the crossover becomes sharper and it moves to larger λ 's due to the increase of correlation effects.

To assess quantitatively the accuracy of the GPW, in Fig. 2 the evolution of m^* as a function of λ for $t = 1.5$ and $\delta = 0.3$ is compared with DMFT. Like in DMFT, the variational m^* first increases with λ in the adiabatic regime, reaches a maximum and finally decreases in the antiadiabatic regime. The GPW results closely follow DMFT for large λ 's, and deviate more appreciably only in the adiabatic region, although the difference with the exact results is never larger than 20%. Yet, the qualitative behavior is correct for any λ ; in particular, as previously mentioned, the polaron-formation remains a crossover also deep inside the adiabatic regime.

The effect of the e-ph coupling on the mass renormalization is hidden in the variational calculation into the overlap $\langle \psi_0 | \psi_0 \rangle$. In Fig. 3 we plot $\langle \psi_0 | \psi_0 \rangle$ as a function of λ for two values of $t = 0.2; 0.6$ within the adiabatic region, where the quantitative agreement with DMFT is poorer. Here we compare with the same quantity from DMFT, and with $m^*(\lambda) = m^*(0)$ calculated in DMFT from the derivative of the self-energy. Obviously within DMFT eq. (10) has no reason to hold. In both cases the variational wavefunction is able to reproduce extremely well the exact value of the overlap. What is clearly different in the two cases is the ability of GPW to reproduce the results

Fig. 3: (Color online) $\langle \psi_0 | \psi_1 \rangle$ as a function of λ at $\delta = 0.3$ for $\gamma = 0.2$ and $\gamma = 0.6$ in GPW (solid black line) and DMFT (dashed red line), compared with $m(0) = m(\lambda)$ from DMFT (dot-dashed blue line)

for the effective mass. While for $\gamma = 0.6$ the agreement is very good also as far as $m(0) = m(\lambda)$ is concerned, which also means that eq. (10) is almost valid within DMFT, for the smaller value of $m(0) = m(\lambda)$ and $\langle \psi_0 | \psi_1 \rangle$ are quite different, and the accurate value of the overlap is not translated into an equally accurate estimate of the effective mass. This result is consistent with the spirit of our variational approach which is not in principle accurate for a quantity related to excitations, such as m , while it correctly reproduces static quantities such as the overlap. Only when the phonon contribution to the mass renormalization $m(\lambda) = m(0)$ can be expressed in terms of the overlap, the method becomes very accurate also for this quantity.

Finally, let us discuss in some details the evolution of the phonon wavefunctions, which are easily accessible within the variational approach. In Fig. 4 the behavior of $\phi_0(x)$ and $\phi_1(x)$ is shown as a function of doping at $\delta = 0.2$ and for three different values of λ , representative of the weak to intermediate to strong-coupling crossover. At $\lambda = 5.6$, deep into the polaronic regime, the phonon wavefunctions are basically harmonic oscillators with a displacement very close to the atomic limit values (marked by the vertical arrows in the figure), and with a negligible doping dependence. Similarly, when the e-ph coupling is relatively small ($\lambda = 0.8$), the wavefunctions are still similar to displaced harmonic oscillators, although the doping dependence is more pronounced. The most interesting behavior occurs for $\lambda = 2.4$, which lies in the crossover region of Fig. 3. Here the shape of the phonon wavefunction strongly deviates from the harmonic oscillator and the doping dependence is strong. In particular, $\phi_0(x)$ develops a shoulder besides the main peak. The position of the shoulder roughly corresponds to the maximum of $\phi_1(x)$. It is exactly this deformation that makes the continuous evolution as a function of λ possible. We notice that a simi-

lar behavior for the evolution of the phonon wavefunction is obtained by means of an exact numerical solution of the polaron problem on a two-site lattice in the Holstein model [18].

Fig. 4: (Color online) Evolution of wavefunctions as a function of doping for different values of λ at $\gamma = 0.2$. The arrows indicate the displacements in the atomic limit.

In this paper we have introduced a generalization of the Gutzwiller variational approach to account for the e-ph coupling besides strong electronic correlations. We have benchmarked the variational wavefunction in the infinite-U limit of the Hubbard-Holstein model on the Bethe lattice, where the variational problem can be solved analytically and directly compared with exact DMFT calculations. We have found that the variational results are in perfect qualitative, and to a large extent also quantitative, agreement with the exact ones. We emphasize that the variational wavefunction (2) treats on equal footing both electronic and phononic coordinates, without assuming either a Born-Oppenheimer scheme or an anti-adiabatic one. From this viewpoint, it may provide interesting insights about the way retardation effects due to the lattice dynamics show up in the ground state wavefunction, especially for strongly correlated systems where the Gutzwiller approach is expected to work better.

We acknowledge precious discussions with S. Ciuchi and G. Sangiovanni. This work has been supported by MIUR Co n 2004 and 2005 and by CNR-INFM.
