E ective Attraction Interactions between Like-charge M acroions Bound to B inary Fluid Lipid M em branes

X ia-qing Shi and Yu-qiang M a National Laboratory of Solid State M icrostructures, Nanjing University, Nanjing 210093, China (Dated: March 23, 2024)

Abstract

U sing integral equation theory of liquids to a binary mixed uid lipid membrane, we study the membrane-mediated interactions between the macroions and the redistribution of neutral and charged lipids due to binding macroions. We not that when the concentration of binding macroions is in nitely dilute, the main contribution to the attractive potential between macroions is the line tension between neutral and charged lipids of the membrane, and the bridging elect also contributes to the attraction. A s the relative concentration of charged lipids is increased, we observe a repulsive - attractive - repulsive potential transition due to the competition between the line tension of lipids and screened electrostatic macroion-macroion interactions. For the nite concentration of macroions, the main feature of the attraction is similar to the in nite dilution case. How ever, due to the interplay of form ation of charged lipid -macroion complexes, the line tension of redistributed binary lipids induced by single macroion is lowered in this case, and the maximum of attractive potential will shift tow and the higher values of the charged lipid concentration.

I. IN TRODUCTION

G enerally, it is believed that, in the physiological condition, biom em branes are quasitw odimensional (2D) uid mixtures, composed of a wide variety of protein and lipid molecular species. The protein-protein, protein-lipid, and lipid-lipid interactions in and on the membranes are very important to the functions of the cell, such as ligand-receptor interactions (1), m em brane rafts (2), and the form ation of lipids dom ains and m em brane budding (3), etc. M ost of these problem s are complex and not well understood yet. Recently, there is an increasing interest in understanding the electrostatic binding of charged m acroions to the oppositely charged lipid membrane both experimentally and theoretically (4-13). Because of lipid's uidity in the membrane, when the charged macroions are bound to the membrane, the oppositely charged lipids would m igrate to the binding sites. This process would compete with the mixing entropic e ects of di erent lipid species, and at equilibrium, the m in im um of free energy is required. There are several theoretical works characterizing such a process (9-13). One of the models takes into account the entropy contributions of lipids and m em brane-associated proteins to the free energy in the incom pressible lim it. C om bined with the nonlinear Poisson-Boltzmann (PB) equation, May and Ben-Shaul have obtained the local lipid composition and the adsorption free energy in the single protein case, and accessed the in uence on these physical quantities when the concentration of binding proteins is nite (9). By introducing a parameter characterizing the extent of non-ideal lipid mixing in the mean eld approximation, they were able to give the phase behavior of charged lipid m em branes with the binding peripheral proteins. The existence of a two-dimensional phase separation suggests that there is an e ective lateral attractive potential between the binding proteins. However, the nonlinear PB theory itself does not introduce such a potential (14), and thus the authors argued that the attraction must be mediated by the membranes (10,12). To num erically solve the nonlinear PB equation simply and e ciently, most of the theoretical work mentioned above adopted cylindrical symmetry with the axis through the center of the macroion and normal to the charged membrane. Such a symmetric consideration make it di cult to calculate the e ective pair potential between the macroions. In fact, there have been no system atic theoretical studies into detailed calculation of e ective interactions between binding macroions. The speci c form of membrane mediated like-charge attractive potential has not been clari ed, and the mechanism is still unclear.

In the present paper, we establish a simple model of the uid membrane and the binding macroions, to exam ine the lipid-mediated elective pair potential between binding macroions. A ctually, the calculation of the elective pair potential is very important to understanding the phase behavior of soft matters. Recently, the elective potential in ionic solution that is beyond the description of the D erigquin-Landau-Verwey-O verbeek (D LVO) theory receives great recognition (15), and it is believed that it will have further applications in biological systems (16,17). The most counterintuitive phenomenon is the elective attraction between like-charge objects. Most of these phenomena can be understood as the strong correlation election of marallel glass walls is still an open question both for experimental and theoretical studies (22-24). It is believed that such a long-range attraction is mediated by the substrate parallel glass walls because of con nem ent, but the mechanism is still not revealed theoretically (16). On the contrary, the theoretical understanding of elective potential between the macroions mediated by the uid membrane will be much more complicated, but is relatively unexplored. There are several approaches to get the elective potential theoretical theoretica

retically. Here we will adopt the integral equation theory which is an accurate and powerful tool to explore the m icroscopic short-range structure of liquids (25,26), and recently, it has been applied successfully to explain the haloing e ects of colloidal stabilization (27,28).

II. MODELAND THEORY

It is well-known that biom embranes are a kind of lyotropic liquid crystals, and the lipid is an amphiphilic molecule composed of a hydrophilic head and one or two hydrophobic tail chains. In our model, we take the membrane as two-dimensional uids composed of neutral and charged lipid species. The interactions between the lipids can be separated into two parts which are head-head and tail-tail interactions. The head-head interactions are treated as 2D hard core, while the tail-tail interactions are treated as 2D soft core to account for the repulsions between the tails originated from both enthalpy and entropy of chains. Thus the total pair potential V (r) between and lipids with a lateral separation r can be written as: 8

$$V (r) = \begin{cases} < 1; & r r_{h} + r_{h}; \\ + v (r); r_{h} + r_{h} < r r_{s} + r_{s}; \\ \cdot v (r); & r > r_{s} + r_{s}; \end{cases}$$
(1)

where the indices and (= c or n), indicate charged or neutral lipids. r_h is lipid's hard-core radius, and r_s is lipid's soft-core radius. is the soft repulsion between

and lipids, therefore the interaction parameter characterizing the demixing extent of non-ideal mixed lipids is given by $!_{cn} = _{cn} (_{cc} + _{nn})=2$. For the sake of sim plicity, we set $_{cc} = _{nn} = 0$, and thus $!_{cn} = _{cn}$. However, we should point out that the real interaction between chains may be more complex as presented in literatures (29-31).v (r) is the elective potential between the lipids introduced by charged heads in the absence of binding macroions, and it is obvious that $v_{nn}(r) = v_{cn}(r) = 0$.

The binding macroions can move, but con ned in a two-dimensional plane which is parallel to the mem brane but with a separation h, as reported in literature (13). For sim plicity, the macroion is modelled as a hard sphere, which is uniform ly charged on the surface. The pair potential V_{pp} (r) between the macroions can be written as:

$$V_{pp}(r) = \begin{cases} 1 ; r & 2r_{p}; \\ v_{pp}(r); r > 2r_{p}; \end{cases}$$
(2)

where r_p is the hard-core radius of the macroion, v_{pp} (r) is the screened electrostatic interaction in the absence of charged lipids. In the binding state, there is another pair potential to account for the interactions between the negatively charged lipids and positively charged macroions. Form ally, it can be written as:

$$V_{pc}(r) = v_{pc}(r;h);$$
 (3)

where r is the lateral separation between the lipids and macroions, and h is the minimal membrane macroion distance (see Fig. 1). When h is xed, the pair potential is only concerned with lateral distance r, so such a system can be e ectively treated as a 2D uid mixtures with pair potentials given above. Now, we can apply the two-dimensional integral equation theory to our model. The O mstein-Zemike (O Z) equations for hom ogeneous

m ixtures in two-dimensional case are given by

h (r) = c (r) + c (jr
$$r^{0}$$
)h (r⁰)dr⁰; (4)

where h (r) is de ned by h (r) g (r) 1.g (r) is the radial distribution function, and h (r) and c (r) are the total and direct correlation function between two particles of species and , respectively. is the number density of species . The sum mation is over all species, and the integral is perform ed over the two-dimensional space. Eq.(4) can be closed by the well-known Percus-Yevick (PY) or hypernetted-chain (HNC) approximations or other therm odynam ic self-consistent approximations (25,26,32) which have dimensional space functions B (r). Form ally, it can be written as follow s:

$$q (r) = e^{V (r) + h (r) c (r) + B (r)}$$
(5)

In the HNC approximation, B (r) = 0, while in the PY approximation, B $(r) = \ln (1 + (r))$ (r) where (r) h (r) c (r).

III. DETAILS OF CALCULATION

0

The rst step to do our calculation is to write down the speci c form of pair potentials. Here, however, we must fall back on some approximations. The most important thing that we care is whether the charges are screened near the membrane in the physiological condition. One might argue that since the charges cannot penetrate into the membrane, the electro-static interactions between charged macroions or lipids near the membrane will not be screened. Such a statement does not take into account the speci c properties of the membrane and the solution. We know that the hydrophobic part of the cell membrane has a dielectric constant "membrane 2:1 and a thickness around 6 membrane while the solution, in the physiological condition, has a dielectric constant "s 80 and the screening length

1 nm (33). When a charge Q occurs in the solution near the membrane (within 3 4 nm), it will form an image charge in the membrane with $Q^0 = \frac{"s}{"s} + "m}_{s} Q$ Q. Now most of screening charges are near the membrane within 1 nm, and these charges would form images in the hydrophobic part of the membrane. Therefore the charges are surrounded by screening charges even on the membrane, and the electrostatic interactions must be more or less screened. This justimes the use of screened potentials. The screened potentials can be written as follows:

$$v_{pp}(\mathbf{r}) = \frac{Z_{p}^{2}L_{B}}{r} e^{r};$$

$$v_{pc}(\mathbf{r}) = \frac{p}{r^{2} + (r_{p} + h)^{2}} e^{p} \frac{r}{r^{2} + (r_{p} + h)^{2}};$$

$$v_{cc}(\mathbf{r}) = \frac{Z_{c}^{2}L_{B}}{r} e^{r};$$
(6)

where the B jerrum length $L_B = \frac{e^2}{4 "_0"_s}$, is the screening length of the solution, and $= 1 = k_B T \cdot Z_c$ and Z_p are the electrive charges of charged lipids and m acroions, respectively.

Substituting Eq.(6) into Eqs.(1)-(3) gives the pair potentials we adopt here. Combined with the hard-core repulsion of macroions, we can study the elects of the screening length, charges, and macroion's size, etc.

The three-component OZ equations are calculated in the k-space. W ith some algebra, it can be written in a form more suitable for numerical calculations, which is form ally given by

$$\tilde{n}(k) = f(;e(k));$$
(7)

where $c(k) = (c_{cn}(k); c_{np}(k); c_{pc}(k); c_{cc}(k); c_{nn}(k); c_{pp}(k))$ and $= (c_{c}; n; p)$. In the limiting p ! 0, the OZ equations in the k-space reduce to a two-component OZ equations of lipids:

$$\tilde{h}_{cc}(k) = \frac{e_{cc}(k) + n(e_{cn}^2(k) - e_{cc}(k)e_{nn}(k))}{D(k)};$$
(8a)

$$\tilde{n}_{nn}(k) = \frac{e_{nn}(k) + c(e_{cn}^{2}(k) - e_{cc}(k)e_{nn}(k))}{D'(k)};$$
(8b)

$$\tilde{n}_{cn}(\mathbf{k}) = \frac{\mathbf{e}_{cn}(\mathbf{k})}{D'(\mathbf{k})}; \tag{8c}$$

and coupling equations with m acroions:

$$\tilde{n}_{pc}(k) = \frac{e_{pc}(k)(1 - ne_{nn}(k)) + ne_{cn}e_{pn}(k)}{D'(k)};$$
(9a)

$$\tilde{h}_{pn}(k) = \frac{e_{pn}(k)(1 e_{c}e_{cc}(k)) + e_{c}e_{cn}e_{pc}(k)}{D^{r}(k)};$$
(9b)

where $D(k) = (1 c_{cc}(k))(1 n_{cn}(k)) c_{cn}(c_{cn}^2(k))$. The two-dimensional Fourier transformation of the isotropic system can be defined by

$$f(\mathbf{r}) = \frac{1}{2} \int_{2^{0} - 1}^{2^{-1}} kf'(\mathbf{k}) J_{0}(\mathbf{k}\mathbf{r}) d\mathbf{k}; \qquad (10a)$$

$$f'(k) = 2 \int_{0}^{1} rf(r) J_0(kr) dr;$$
 (10b)

where $J_0(x)$ is the zeroth-order Bessel function of the st kind. In num erical calculations, Eq.(10) is truncated and discretized in r-space and k-space. The discrete Fourier transform ation adopt here is a slow m ethod, but satis es the orthogonality conditions (34,35) which are important in our calculation.

The OZ equations (8) are closed by the well-known PY approximation, which is good for short-range potential and predicts with a reasonable accuracy both structural and therm odynamic properties of the investigated system (25). For the short-range repulsion between the lipids studied here, it is obvious that the PY approximation is more suitable. On the other hand, macroion's elect can electively be treated as an external eld, and thus Eqg) is solved by combining with HNC approximation (26), which is better for the long-range potential. Finally, the integral equations are solved by using the Picard iteration scheme, and the equality (5) can be rewritten as follows:

$$c^{\text{new}}(\mathbf{r}) = p[e^{V(\mathbf{r}) + (\mathbf{r}) + B(\mathbf{r})} - 1(\mathbf{r})] + (1 - p)c^{\text{old}}(\mathbf{r});$$
 (11)

where p is an adjustable parameter to achieve the best perform ance of iterations.

IV. RESULTS AND DISCUSSION

In the in nite-diluted case, the coupling between macroions has been ignored, and thus the distribution function of macroions can e ectively be dened by $g_p(r) = e^{V_{pp}^{eff}(r)}$. Because of the coupling between the macroions and the lipids, the explicit distribution function is written as follows:

$$g_{pp}(\mathbf{r}) = e^{V_{pp}(\mathbf{r}) + c \int h_{pc}(\mathbf{r}^{0}) c_{pc}(\dot{\mathbf{r}} - \mathbf{r}^{0}) d\mathbf{r}^{0} + n \int h_{pn}(\mathbf{r}^{0}) c_{pn}(\dot{\mathbf{r}} - \mathbf{r}^{0}) d\mathbf{r}^{0}};$$
(12)

7

namely the e ective pair potential between m acroions is

$$V_{pp}^{eff}(\mathbf{r}) = V_{pp}(\mathbf{r}) \quad {}_{c} \quad h_{pc}(\mathbf{r}^{0})c_{pc}(\mathbf{j}\mathbf{r}-\mathbf{r}^{0}\mathbf{j})d\mathbf{r}^{0} \quad {}_{n} \quad h_{pn}(\mathbf{r}^{0})c_{pn}(\mathbf{j}\mathbf{r}-\mathbf{r}^{0}\mathbf{j})d\mathbf{r}^{0}$$
(13)

Here, the e ects of the lipids on the macroions have been included in the e ective pair potential between the macroions.

In the calculations presented below, we will restrict ourselves to the case that di erent species of lipids have the same size, $r_{ch} = r_{nh} = -$, $r_{cs} = r_{ns} = 4 = 3$. The macroion's radius $r_p = 4$ and them inim almembrane macroion distance h = 0.3. The Fourier transform ation is truncated at r = 90. The choice of the soft-core range seems a bit arbitrary, however, since such a range is xed during our calculation, it will not obscure the results given below. To keep in line with the data appeared in Ref. (12), we choose $r_{ch} = r_{nh} = -4$.

In Fig.2 we show the elective potentials $V_{pp}^{eff}(r)$ and the mem brane-mediated potential $V_{pp}^{m}(r) = V_{pp}^{eff}(r)$ $V_{pp}(r)$ for varying values of the demixing strength $!_{cn}$ between neutral and charged lipids in the physiological condition (= 10A; T = 300K). The lipid concentration is xed to be $_{c}^{2} = 0.055$ for charged lipids and $_{n}^{2} = 0.105$ for neutral lipids. We see that with increasing the repulsion between the neutral and the charged lipids, the attraction between macroions is greatly enhanced. The result supports the conclusion made by H inderliter (7,8) from experiments and M onte-C arlo simulations. Obviously the elective potential is composed of two parts: one is from the contribution of the screened potential between macroions, and the other is mediated by the substrate membrane. The membrane-mediated attraction between macroions is within 4 5 lipid's diameter from their surfaces.

Figure 3 shows the total correlation functions h_{pc} and h_{pn} with the lateral separation between macroion and lipid for dierent values of $!_{cn}$. The correlations increases with the increase of $!_{cm}$. Therefore, we can say that the attraction is mediated by the membrane through the correlations between the macroions and lipids. The resulting local density lipids which deviates from the averaged bulk density distribution (r) of the , can be obtained by the relation $(r) = (h_p (r) + 1)$, when a macroion is in the center (r = 0). Interestingly, the density distribution of the lipids under the macroions is greatly modi ed by increasing the unm ixing interaction ! ... between neutral and charged lipids, while the electrostatic interactions between the macroions and charged lipids keep unchanged. As ! cn = 0, the solid line in Fig. 3 shows that the enrichm ent of charged lipids appears below the macroion, just through the screened C oulom b potential. Such a process can be balanced by the reduction of the mixing entropy and the increase of the repulsions between charged lipids. As ! cn turns on, it has a tendency to drive the same lipids to aggregate together. This will greatly increase the macroion-lipid correlations, as shown in Fig. 3, by enhancing the aggregation of the same lipids, due to a pre-enrichment of charged lipids below the macroion at $!_{cn} = 0$.

The density pro-less obtained here is similar to the results obtained from numerical solutions of the Poisson-Boltzm ann equation (12,13). However in the present case, we have taken into account the correlation elects of species, and from the inset of Fig. 3 (b), we indicate the number density of charged lipids, there is a depleted region of charged lipids where the number density of charged lipids is even smaller than the bulk case. Such a depleted elect of charged lipids will become estronger if the correlation elect is enhanced, as shown in Fig. 4 when Z_c is increased to 2e. This is in agreement with the statement about the multivalent system where the charge correlations become elimportant, and thus there exists some counter-intuitive elects (16), which are beyond the descriptions of the PB theory.

For inhom openeous mixing lipid system, if the interface between neutral and charged lipids is absolutely sharp on a molecular scale, the line tension will be directly proportional an attractive e ect can be enhanced by the line tension between di erent lipids. However, the weak attraction exists, even for the case $!_{cn} = 0$ where the line tension contributes little to the attraction. It indicates a deeper screening of the interactions between binding m acroions in the presence of charged lipids. The origin of such a potential is due to the bridging e ect of charged lipids, namely two macroions jointly attract to the same set of charged lipids (28). Intuitively, it seems that there exists another e ect, the so-called depletion attractive interaction (36), to contribute to V_{pp}^{m} (r). If we take the charged lipids-rich clusters under the binding macroions as static, it is possible to introduce such a depletion e ect by hardcore repulsions between the clusters and the surrounding lipids. However, such a picture is naive. The charged lipids rich regime is not static, but quite dynamic. The charged and neutral lipids can move in and out of the regime quiet freely, although the density pro les remain unchanged. Therefore, there is no static interactions between the charged lipids-rich regimes and the surrounding lipids. Such a dynamic e ect is similar to that of Karanikas and Louis (28). To illustrate it clearly, we eliminate the bridging e ect by introducing a pseudo potential between the binding m acroions and the charged lipids:

⁸
⁴
$$V_{pc}(r) = p \frac{Z_p Z_c L_B}{r^2 + (r_p + h)^2} e^{p \frac{1}{r^2 + (r_p + h)^2}}; r 2r_p;$$

¹ $V_{pc}(r) = 0;$ $r 2r_p;$ (14)

Such a potential does not allow two m acroions to attract the same set of charged lipids, but the charged lipids-rich regime still exists. W hen we apply such a potential to our model in the case $!_{cn} = 0$, the weak attraction disappears. This means that the bridging e ect is dom inant and there is no depletion e ect under the present dynam ic picture.

In Fig. 5, we change the relative composition of neutral and charged lipids, but the total number density of lipids is xed. Interestingly, when $_{\rm c}$ is low, the elective potential is mainly repulsive, where the screened potential dominates over the interactions between macroions. W ith the increase of charged lipids, the membrane-mediated attraction becomes signi cant, and it competes with the screened potential at a distance about 2 -6 and then forms an attractive well at that range. The attractive force saturates when $_{\rm c}^2 = 0.05$. Further increase of charged lipids will weaken the attractive potential, because the screened potential begins to dominate the system again.

To clarify the dom inant contribution to the attractive potential, we can calculate the line tension by varying the number density of charged lipids, but $!_{cn}$ is xed. In the continuum limiting, the line tension is given by $_1 = C (!_{cn}) dr(r_c(r))^2$, where $_c(r)$ is the local composition of charged lipids, and is estimated by $_c(r) = _c(r) = (_c(r) + _n(r))$.

C ($!_{cn}$) is a coe cient relevant to $!_{cn}$, here it is a constant, and thus we will present the result of $_1(\mathbf{r})$ in units of C (! a). In Fig. 6, the solid square line tension curve $_1(\mathbf{r})=C$ (! a) is plotted as a function of the number density of charged lipids for the in nite-diluted case ($_{\rm p}$ 2 ! 0). The line tension rst increases with $_{\rm c}$ 2 , and then is decreased. The maximum line tension almost correspond to the deepest attractive potential of lipid-mediated interactions between m acroions in Fig.5, and they are of the same order. We can conclude that the attractive potential increases with the line tension, depending upon two factors: the dem ixing interaction and the relative component between neutral and charged lipids. On the other hand, the e ective attractive potential between m acroions is always enhanced by increasing charged lipid's concentration c^2 , namely the attraction due to the bridge e ect monotonously increases with $_{\rm c}$ ². Therefore, there is a cooperation between the line tension and the bridging e ect which pintly assists the attraction between m acroions at the beginning stage of the increase of $_{\rm c}$ ², and for relatively large values of $_{\rm c}$ ², a competition occurs, since line tension will decrease with further increase of charged lipids. The fact that the line tension behavior in Fig.6 is in accordance with the e ective potential well vs $_{c}^{2}$ in Fig.5, clearly indicates that the line tension plays a vital important role in the membrane-mediated potentials, as argued in the Ref. (12) in the continuum limits of the membrane.

We now turn to discuss the elects of nite macroion concentration. In this case, the coupling between macroions cannot be ignored, and we have to solve the three-component O Z equations. The elective potential V_{pp}^{eff} between macroions can be obtained by an inverse process (37). A fler solving the integral equation Eq.(7), we can obtain the total correlation function $h_{pp}(r)$, and then the direct correlation function $e_{eff}(k)$ can be solved from the reduced one-component O Z equation:

$$e^{\text{eff}}(\mathbf{k}) = \frac{\tilde{n}_{pp}(\mathbf{k})}{1 + {}_{p}\tilde{n}_{pp}(\mathbf{k})}$$
 (15)

The e ective potential can be solved from the HNC approximation (24,37):

$$q_{\rm DD}(\mathbf{r}) = e^{V_{\rm pp}^{\rm eff}(\mathbf{r}) + h_{\rm pp}(\mathbf{r}) \ c^{\rm eff}(\mathbf{r})}$$
(16)

As p! 0, the present calculation reduces to the in nite-diluted case.

In Fig. 6, we rathy show the line tension as a function of $_{\rm c}$ ² for di erent m acroion concentrations. We notice that on increasing binding m acroions, the line tension is gradually decreased and the position of the m axim um line tension shifts toward the higher values of $_{\rm c}$. These two behaviors are of the same origin, because there exists a competing interplay of di erent m acroions to recruit charged lipids. The competition will partially suppress the modi cation of lipid composition probes induced by a single m acroion, and thus the line tension decreases, in comparison with the case $_{\rm p}$ ² ! 0. Furthermore, we can expected that, at lower m acroion concentrations, the charged lipid's probes a single of $_{\rm c}$ ². However, if the m acroion concentration is increased, the charged lipid's concentration will not saturate at a form er value of $_{\rm c}$ ². To achieve the m axim um line tension occurs with a higher value of $_{\rm c}$ ² with the increase of binding m acroions.

In Fig.7 we depict the e ective potential for varying values of $_{\rm c}$ ² when $_{\rm p}$ ² = 0:004. We can see that the change of ective potentials has the same tendency as in the in nite-diluted

case. When the concentration of charged lipids is low, the screened Coulomb potential dominates, and the elective potential is repulsive. In an intermediate concentration, the membrane-mediated attractive potentials compete with the screened Coulomb potentials and form an elective attractive well. With further increase of charged lipids, the mediated attractive potentials decay, and the screened Coulomb potentials dominate over the system again. If we calculate the line tension in this case, also, it has the same tendency as in the in nite-diluted case. However, we see from Fig.7 that on increasing the binding macroions, the attractive potential saturates at a certain concentration with $_{\rm c}^{2} = 0.08$, which deviates slightly from the value $_{\rm c}^{2} = 0.07$ where the line tension is maximum (Fig. 6). Such a deviation indicates that although line tension is still dominant for nite concentration of macroions, the bridge elect will become relatively stronger, compared to the in nite-diluted case.

V. CONCLUSION

In this paper, we have studied the membrane mediated potential between the binding m acroions which is induced by the interplay of the macroions and lipids. The process can be generally interpreted as follows. When the binding macroions are in nite dilute, the m acroion will induce an enrichm ent of charged lipids under it. This process will be balanced by the decrease of the mixing entropy and the increase of repulsion between charged lipids. W hen there is a soft-core repulsion between charged and neutral lipids, the nonuniform distribution of lipids will introduce a line tension. Them acroions prefer to appregate together to reduce the line tension energy. This will compete with the screened Coulomb potential and form an attractive well in the e ective potential. The bridging e ect will also contribute to the attractive potential, but the line tension is dominant. Interestingly, as we increase the num ber density of charged lipids, but x the total num ber density of lipids, we observe a repulsion - attraction - repulsion transition due to the competition between the line tension and screened electrostatic interactions. For the nite concentration case, we have to take into account the coupling e ects between binding macroions. We nd that with the increase of binding macroions, the line tension induced by a single binding macroion is gradually suppressed and the maximum of attractive potential will shift toward the higher values of charged lipid concentration c. The result can be attributed to the competition of recruiting charged lipids due to di erent binding macroions. The e ective potential calculated in this case is not as faithful as the in nite dilution case. But in the case where the concentration of binding macroions is xed, the result obtained is physically reasonable.

Figure 1: Schem atic of a macroion bound to a binary uid lipid membrane. The lipid is treated as a hard-sphere head with a radius of r_{ch} (charged lipid) or r_{nh} (neutral lipid) and a soft-core repulsion tails. The binding macroions are treated as uniform ly charged hard spheres with radius r_p . There is a separation h from the membrane to the bottom of the macroion. The system is a three-dimensional system, but can be electively mapped into a two-dimensional one when h is xed.

Figure 2: The elective pair potentials $V_{pp}^{eff}(\mathbf{r})$ or $V_{pp}^{m}(\mathbf{r}) = V_{pp}^{eff}(\mathbf{r})$ volume $V_{pp}(\mathbf{r})$ change with $!_{cn}$. The macroion's diameter is chosen to be 8, and the elective charges of the macroions and charged lipids is $Z_p = 6e$ and $Z_c = 1e$, respectively. The mediated potential $V_{pp}^{m}(\mathbf{r}) = V_{pp}^{eff}(\mathbf{r})$ $V_{pp}(\mathbf{r})$ becomes more attractive with the increase of $!_{cn}$. This is a general behavior of the system.

Figure 3: The total correlation functions $h_{pn}(r)$ and $h_{pc}(r)$ between the lipids and macroion for varying values of $!_{cn}$. In (b), the curves for the lateral distance r > 12 is enlarged, and re-plotted in the inset, showing the correlation elects which will not appear in the mean eld approximation.

Figure 4: The total correlation function $h_{pc}(r)$ verse $!_{cn}$ for $Z_c = 2e$.

Figure 5: E ective pair potential $V_{pp}^{eff}(r)$ verse the number density of charged lipids for xed total lipids concentration $(_{c} + _{n})^{2} = 0.16$ and $!_{cn} = 2.0$. The attractive potential saturates at an interm ediate concentration $(_{c}^{2} = 0.05)$ of charged lipids.

Figure 6: Single macroion induced line tension as a function of $_{\rm c}$ ² for xed total lipids concentration ($_{\rm c}$ + $_{\rm n}$)² = 0:16 and $!_{\rm cn}$ = 2:0. The solid square curve shows the case $_{\rm p}$ ²! 0, and the line tension saturates at $_{\rm c}$ ² = 0:05. As the binding macroions are increased, The line tension decreases, and the position of maximum line tension moves toward the higher values of $_{\rm c}$ ².

Figure 7: E ective pair potential $V_{pp}(r)$ for varying concentrations of charged lipids with $(_{c} + _{n})^{2} = 0.16$, $!_{cn} = 2.0$, and $_{p}^{2} = 0.004$. The attractive potential saturates at an interm ediate concentration $_{c}^{2} = 0.08$.
