(Dated: April 15, 2024)

U sing ground-state projector quantum M onte C arb simulations in the valence bond basis, it is demonstrated that non-frustrating four-spin interactions can destroy the Neel order of the twodimensional S = 1=2 H eisenberg antiferrom agnet and drive it into a valence-bond solid (VBS) phase. Results for spin and dimer correlations are consistent with a single continuous transition, and all data exhibit nite-size scaling with a single set of exponents; z = 1; = 0:78 0:03, and = 0.26 0:03. The unusually large and an emergent U (1) symmetry, detected using VBS order parameter histogram s, provide strong evidence for a decon ned quantum critical point.

PACS num bers: 75.10.-b, 75.10.Jm, 75.40 Mg, 75.40.Cx

Since the discovery in 1986 of high-T_c superconductivity in layered cuprates, quantum phase transitions in twodim ensional (2D) antiferrom agnets have form ed a central topic in condensed m atterphysics [1, 2]. W hile superconductivity is induced in the CuO₂ planes of the cuprates by doping with charge carriers, other mechanisms for destroying the Neel order and stabilizing di erent ground states have also been intensely investigated theoretically. Considerable e orts have been devoted to possible spin liquid ("RVB" [3]) and valence-bond solid (VBS) states driven by magnetic frustration [4, 5, 6]. This work has been partially motivated by the hope that an understanding of generic features of quantum phase transitions in 2D antiferrom agnets could shed light also on the mechanism s at work in the cuprates [7]. Quantum uctuation driven phase transitions are also of broader relevance in the context of strongly correlated system s [8].

A quantum phase transition occurs as a function of som e param eter at tem perature T = 0 and corresponds to a T > 0 transition in an e ective classical system with an in aginary-timed in ension the path integral [9]. The standard Landau-G inzburg-W ilson fram ew ork for critical phenom ena should thus be applicable, with the dim ensionality d! d + z, where the dynam ic exponent z depends on the way space and time correlations are related. In the paradigm prevailing until recently, the \Landau rules" for the nature of the transition continuous or rst-order were also assumed to remain valid for quantum phase transitions. A direct transition between two ordered phases should thus be generically rst-order if two di erent symmetries are broken. This notion has recently been challenged by Senthil et al., who argued that quantum phase transitions separating two ordered phases can be generically continuous, even when di erent symmetries are broken [10]. This theory of \deconned" quantum critical points was rst developed for the transition between an antiferrom agnetic (AF) and a valence-bond-solid (VBS) state. Both these states have con ned S = 1 excitations gaplessm agnons and gapped "triplons", respectively. The critical point is characterized by decon ned S = 1=2 spinons coupled to an emergent U (1) gauge eld [10]. In 2D the decon ned state is unstable and exists only at a point separating the two ordered phases. The AF and VBS order parameters arise as a consequence of spinon con nem ent. In this Letter, quantum M onte C arlo (QMC) results are presented which support this theory.

Preceding the theory of decon ned quantum critical points, continuous transitions between two ordered quantum states had been suggested based on num erical sim ulations [11, 12]. However, in more detailed studies following the theoretical developments it has proved di cult to con m their existence. Instead, many studies have pointed to weakly rst-order AF {VBS transitions [13, 14, 15, 16, 17] or other scenarios inconsistent with decon ned quantum criticality [18]. To date, large-scale QMC studies of potential decon ned quantum critical points have focused on spin (or hard-core bosonic) models with spin-anisotropic interactions [13, 14, 15, 16]. Frustrated SU (2) (Heisenberg) sym metric interactions, which cannot be studied using QMC simulations due to the infam ous "sign problem ", have been considered in exact diagonalization studies [19]. Because of the lim itations to very small lattices, it has not been possible to study phase transitions in detail, however. In fact, not even the nature of the VBS state has been completely settled in basic models such as the $J_1 - J_2$ frustrated Heisenberg m odel [20].

Here it will be shown that the AF order of the squarelattice Heisenberg model can be destroyed also by nonfrustrated isotropic interactions accessible to QMC sim ulations. The following Ham iltonian will be discussed:

v

$$H = J S_{i} S Q (S_{i} S \frac{1}{4}) (S_{k} S \frac{1}{4}); (1)$$
hiji hijkli

where hiji denotes nearest-neighbor sites and hijk li refers to the corners of a plaquette, such that ij and klform two parallel adjacent horizontal or vertical links. This interaction contains a subset of the four-site ring-exchange, and with Q > 0 there is no QMC sign problem. Note

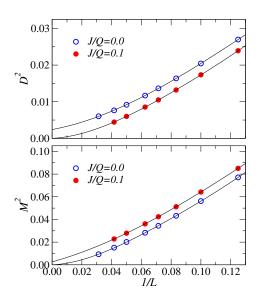

FIG.1: (Color online) Finite size scaling of the squared spin (M) and dimer (D) order parameters at J=Q = 0 and 0:1. The curves are cubic ts. Statistical errors are much smaller than the symbols.

that the purpose here is not to model any speci c m aterial, but simply to construct a model system in which an AF {VBS transition can be investigated. It will be shown below that the ground state of the J-Q model has AF order for J=Q & 0.04 and VBS order for J=Q . 0.04.

To study the ground state of the ham iltonian (1), an approximation-free projector technique in the valence bond basis [21] is employed which is ideally suited for multi-spin interactions formed out of singlet projection operators ($S_1 \quad S \quad \frac{1}{4}$). Here L L lattices with L up to 32 are considered. Larger system s may be reachable using loop algorithm s in the standard S^z basis, which have been used for U (1) models with four-site interactions [22, 23]. The valence bond basis has its advantages, however, including an improved estimator for the singlet{triplet gap.

Results will be presented for spin-spin (s) and dimerdimer (d) correlation functions,

$$C_{s}(r) = hS(0) \quad S(r)i;$$
 (2)
 $C_{s}(r) = hS(0) \quad S(0)S(r) \quad S(r+2)i;$ (3)

where \hat{x} denotes a lattice unit vector in the x direction. The AF order parameter is the staggered m agnetization, the square of which is calculated;

$$M^{2} = \frac{1}{N} \sum_{r}^{X} C_{s}(r) (1)^{r_{x} + r_{y}} :$$
(4)

The VBS state can have either columnar or plaquette order, both of which break Z_4 symmetry. An important aspect of the theory is that these order parameters should both exhibit divergent uctuations at the deconned critical point. Only at some length-scale diverging as a power of the correlation length should one of them

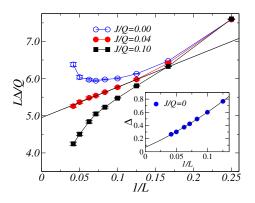

FIG.2: (Coloronline) Finite size scaling of the singlet-triplet excitation gap multiplied by the system size L.The behavior at J=Q = 0.04 corresponds to z = 1.

be singled out [10]. This is analogous to the irrelevance of Z_4 anisotropy in the 3D XY model [26] and corresponds directly to the predicted emergent U (1) symmetry. The q = (; 0) dimer order parameter,

$$D^{2} = \frac{1}{N} \sum_{r}^{X} C_{d}(r) (1)^{r_{x}};$$
 (5)

is divergent for both colum nar and plaquette VBS order and will be studied here.

Extrapolations of the AF and VBS order parameters, shown in Fig. 1, demonstrate that there is long-range VBS order but no AF order at maxim al four-spin interaction; J=Q = 0 (note that there are still two-site interactions present when J = 0; simulations for J < 0 are sign problem atic). A lso shown are results at J=0 = 0:1, where the situation is the reverse; there is AF order but the VBS order vanishes. Thus there is an AF {VBS transition somewhere in the range 0 < J=Q < 0:1, or there could be a region of AF/VBS coexistence (which would be analogous to a supersolid state). The nature of the VBS order columnar or plaquette is not clear from these calculations. However, simulations of openboundary rectangular lattices, in which a unique colum nar or plaquette pattern can be stabilized [12], indicate that colum nar order is preferred. The extrapolated VBS correlation at J=Q = 0 is D^2 0:0024.

The decon ned theory has dynamic exponent z = 1 [10]. This exponent can be directly accessed through the nite-size scaling of the singlet {triplet gap; L^z. To demonstrate consistency with z = 1, the scaling of L is shown in Fig. 2 for J=Q = 0 and 0:1, as well as for J=Q = 0:04 which will be shown below to be close to criticality. Here L extrapolates to a non-zero value, supporting z = 1, and at J=Q = 0 and 0:1 the behaviors are what would be expected o criticality. The inset of Fig. 2 shows an in nite-size extrapolation of the gap at J=Q = 0, giving =Q 0:07.

C orrelation lengths $_{\rm s}$ and $_{\rm d}$ for spins and dimers are de ned in the standard way as the square-roots of the second moments of the correlation functions (2) and (3).

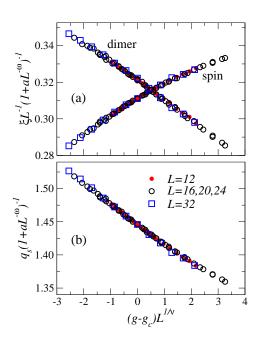

FIG.3: (Color online) Scaling with = 0.78 and $g_c = 0.04$ of the correlation lengths (a) and the spin B inder ratio (b).

A lso useful is the B inder cum ulant, de ned for the spin as $q_s = hM^{-4}i=hM^{-2}i^2$. Finite-size scaling of these quantities is used to extract the critical coupling and the correlation length exponent . To achieve good data collapse, a subleading correction is also included. W ith g = J=Q, the scaling ansatz is,

$$A(g;L) = L(1 + aL')f[(g q)L^{1=}];$$
 (6)

where $A = {}_{s}$; d, or q_{s} , and = 1 for ${}_{s}$; d and 0 for q_{s} . A s seen in F ig. 3, these quantities can be scaled using $q_{c} = 0.040 \quad 0.003$ and a common $= 0.78 \quad 0.03$. In all cases, the subleading exponent ! 2, and the scaling is nearly as good if ! = 2 is xed throughout. Interestingly, the best prefactor a is then almost equal for ${}_{s}$ and ${}_{d}$, a 8, but this may be coincidental.

Next, the correlation functions $C_{s;d}(r)$ at the longest lattice distance, r = (L=2; L=2), are analyzed to extract the correlation function exponent . The expected scaling is as in Eq. (6) with = (1 +). Now g and are kept xed at the values determ ined above. As shown in Fig. 4, a single exponent describes both the spin and dim er data, and in this case a subleading correction is not needed (a = 0). The exponent, = 0:26 0:03. is unusually large. In the 3D O (3) universality class, describing transitions between the AF and a featureless gapped state [1, 24], 0:04. A larger for decon ned quantum criticality was argued for on physical grounds by Senthilet al. [10]. The universality class was argued to be that of the hedgehog suppressed 0 (3) transition, for which = = (1 +)=2 = 0.800:05 was obtained in simulations of a classical model in [25]. This is larger than = 0.63 0.02 found here, but on the other hand sm aller lattices were used in [25] and there may also be

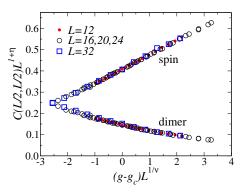

FIG.4: Long-distance spin and dim er correlations scaled using = 0:78, = 0:26, and $g_c = 0:04$.

issues with how hedgehogs were suppressed. The direct study of an actual AF {VBS transition presented above can thus be expected to be more reliable.

It is also interesting to study the probability distribution P ($D_x; D_y$) of the dimerorder parameter. In the VBS phase, one would expect this distribution to reject the Z₄ symmetry, i.e., for a columnar VBS there should be peaks at $D_x = 0; D_y = D$ and $D_x = D; D_y = 0$ (whereas a plaquette state would give rise to peaks rotated by 45). It should be noted, however, that P ($D_x; D_y$) is a basis dependent function. In the valence bond simulations [21] the order parameters used to construct P ($D_x; D_y$) are matrix elements (with $e = x; \hat{y}$),

$$D_{e} = \frac{h_{b} \frac{1}{N} F_{r} S(r) S(r+e) (1)^{r_{e}} j_{a}i}{h_{b} j_{a}i}; \quad (7)$$

where j_ai, j_bi are valence bond states generated by operating with a high power Hⁿ on trial state (stochastically sampling valence bond evolutions). Although $P(D_x; D_y)$ is not a physically measurable quantity, any symmetry detected in it should relect an underlying symmetry of the projected state. Fig. 5 shows a color-coded $P(D_x;D_y)$ histogram generated at J=Q = 0. The expected Z₄ sym m etry of the VBS is not seen; instead the histogram is ring shaped, which indicates a U (1) symmetric order param eter. Such an em ergent U (1) sym m etry is in fact predicted [10] by the decon ned theory in the VBS phase below a length scale which diverges faster than the VBS correlation length; d^{a} , with a > 1. Thus, inside the VBS phase, if the system length L one should expect to nd an U (1) sym m etric order param eter, with the Z4 becoming relevant only for larger sizes (and then seen as four peaks emerging in the histogram). Here, apparently, even at J=Q = 0 the system is close enough to the critical point for the system length (L = 32) to be less than and, hence, Z_4 to be irrelevant. Recalling that the VBS gap is sm all, =Q 0:07, a d ^a, this seems reasonable. On and that moving closer to the critical point, $P(D_x; D_y)$ smoothly evolves into a single broad peak centered at (0;0), as is expected for a continuous transition. Note that the

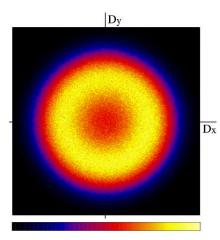

FIG.5: (Color online) H istogram of the dimer order parameter for an L = 32 system at J=Q = 0. The ring shape demonstrates an emergent U (1) symmetry, i.e., irrelevance of the Z₄ anisotropy of the VBS order parameter.

nite-size extrapolation of the order parameter in Fig. 1 is not sensitive to the nature of the VBS state | plaquette or colum nar | and should give the correct m agnitude of the order parameter even though no Z_4 features are yet seen in the histogram for these system sizes.

The above analysis points consistently to a decon ned quantum critical point as the most likely scenario for the AF {VBS transition in the J-Q model. One set of exponents describes both spin and dim er correlations, the value of is unusually large, and there is an emergent U (1) symmetry in the VBS order parameter. In principle one cannot rule out a weakly rst-order transition on the basis of nite-size data. However, although the lattice sizes used in this work are not extremely large, it would be hard to explain why a rst-order transition should lead to the kind of scaling observed. A narrow region of AF/VBS coexistence is also unlikely, as there would then be two transitions and there is no reason to expect the spin and dimer critical exponents to be the same (in particular, the unusually large). It is di cult to say anything more quantitative regarding a possible rst-order transition or coexistence based on the calculations presented here.

An emergent U (1) symmetry may also explain why it has been so di cult to determ ine the nature of the VBS state in the J_1 - J_2 Heisenberg model [20]. Even if the transition would be weakly rst-order in this case [17, 27], an emergent U (1) symmetry could still a ect sm all lattices, thus making it di cult to distinguish between colum nar and plaquette VBS patterns. Emergent U (1) symmetry may be more common than decon ned quantum criticality and could hence a ect many models with VBS states. The high density of low -lying singlets associated with U (1) symmetry may also a ect exact diagonalization studies [6] of level spectra.
