Abstract. The spatial sensor characteristics of a 6cm TDR at band cable sensor section was simulated with finite element modelling (High Frequency Structure Simulator-HFSS) under certain conditions: (i) in direct contact to the surrounding material (air, water of different salinities, different synthetic and natural soils (sand-silt-clay mixtures)), (ii) with consideration of a defined gap of different size filled with air or water and (iii) the cable sensor pressed at a borehole-wall. The complex dielectric permittivity $\epsilon^*(\omega; \epsilon')$ or complex electrical conductivity $\sigma^*(\omega; \sigma') = i\omega\epsilon^*(\omega; \epsilon')$ of the investigated saturated and unsaturated soils was examined in the frequency range 50MHz-20GHz at room temperature and atmospheric pressure with a HP 8720D-network analyser. Three soil-specific relaxation processes are assumed to act in the investigated frequency-temperature-pressure range: one primary α -process (main water relaxation) and two secondary (β , γ)-processes due to clay-water-ion interactions (bound water relaxation and the Maxwell-Wagner effect). The dielectric relaxation behaviour of every process is described with the use of a simple fractional relaxation model. 3D finite element simulation is performed with a $\Delta t=3$ based adaptive mesh refinement at a solution frequency of 1MHz, 10MHz, 0.1GHz, 1GHz and 12.5GHz. The electromagnetic field distribution, S-parameter and step responses were examined. The simulation adequately reproduces the spatial and temporal electrical and magnetic field distribution. High-lossy soils cause depending on increasing gravimetric water content and bulk density an increase of TDR signal rise time as well as a strong absorption of multiple reflections. Air or water gap work as quasiwave-guide, i.e. the influence by surrounding medium is strongly reduced. Appropriate TDR-traveltime distortions can be quantified.

Keywords: lossy dielectrics, finite element modelling, HFSS, dielectric spectroscopy, fractional relaxation

1. Introduction

Soil science, geophysical prospecting, agriculture, hydrology, archeology and geotechnical engineering have benefited greatly from developments in radio and microwave technology. Electromagnetic techniques are used to estimate soil and rock physical characteristics such as water content, density and porosity ([47], [37], [27], [25]). Both invasive methods, such as time domain reflectometry ([49], [40], [15]) and cross borehole radar [10], and noninvasive methods, such as capacity methods ([46], [25], [27]) and ground penetrating radar ([24], [2], [42], [6], [13]) are used. Common to all these techniques is the fact that electromagnetic wave interaction depends on dielectric properties of rock or soil deposit through which it travels, which are influenced by chemical composition, mineralogy, structure, porosity, geological age and forming conditions. Besides, several additions like ubiquitous water have an effect on the dielectric properties.

In particular, knowledge of the spatial and temporal variability of water saturation in soils is important to obtain improved estimates of water flow (and its dissolved components) through the vadose zone. Due to its accuracy and potential for automated measurement, TDR has become one of the standard methods to measure spatial and temporal variability of water contents in laboratory soil cores and experimental field plots [15]. For this purpose, the object of numerous experimental and theoretical investigations is the development of general dielectric mixing models for a broad class of soil textures and structures ([49], [43], [50]). Mostly, these empirical, numerical or theoretical models base on the assumption of a constant dielectric permittivity of the soil as a function of volumetric water content in a narrow frequency range around 1 GHz ([44], [48], [4], [9], [39]). However, the strong frequency dependence in the dielectric relaxation behaviour below 1 GHz due to a certain amount of swelling clay minerals in nearly each real soil is considered only insufficiently ([30], [15], [32], [25]).

The type of multi-scale structure renders the analysis of dynamic data in clays rather complex. The problem has been addressed both by experimental and modelling techniques. Besides broadband dielectric spectroscopy on clay-water suspensions microscopic simulations of clays have been an active field of research since the late 1980s and began with simulations at ambient temperature and pressure, of clays with various cationic species. More recently, several studies appeared dealing with non-ambient conditions (increased temperatures and pressures), which are primarily linked to the issue of storage of radioactive waste or bore-hole stability [35]. Previous experimental and modelling results suggest that clay-water systems have multiple relaxation processes, such as interfacial polarizations around the clay particles and rotational relaxation of bound and free H_2O . Therefore, the dielectric behavior is expected to be complicated. Useful and precise dielectric information may only be obtained when each relaxation process is extracted from the complicated overall behavior based on the measurement of the complex dielectric permittivity over a broad frequency range and at high resolutions ([22], [21], [34], [33]).

In the present study, the dielectric relaxation behaviour of the investigated saturated and unsaturated soils was examined in the frequency range 50 MHz–20 GHz. To parameterize the dielectric spectra three soil-specific relaxation processes are assumed to act as a function of water saturation and porosity in the investigated frequency-temperature-pressure range: one primary process (main water relaxation) and two secondary (ρ , γ)-processes due to clay-water-ion interactions (bound water relaxation and the Maxwell-Wagner effect). The dielectric relaxation behaviour of every process is described with the use of a simple fractional relaxation model ([22], [21], [23], [19], [16]). The chosen approach enables a characterization of the dielectric relaxation behaviour with the separation in the observed relaxation processes in dependence of the porosity and the water content.

A simplification frequently utilized in TDR applications is the use of an idealized equivalent circuit for the sensor without consideration of losses due to the skin-effect or radiation from the sensor as well as the assumption of a homogeneous sensitivity distribution along the sensor ([15], [20], [45], [28]). In addition, a frequently arising problem in various applications is the direct contact between sensor, e.g. a flexible band cable, and surrounding medium. An air or water gap between sensor and soil leads to dramatic under or overestimation of water content. A suitable tool for an examination of this specific problem offers three-dimensional numeric finite element simulation ([28]). For these reasons, in this study the spatial sensor characteristics of a 6 cm TDR flat band cable sensor section was simulated with electromagnetic finite element modelling (Ansoft-HFSSTM, High Frequency Structure Simulator). In order to carry out the finite element calculations as realistically as possible, the measured frequency-dependent dielectric permittivity was considered. Moreover, the simulations were performed under certain conditions: (i) in direct contact to surrounding material, (ii) with consideration of a defined gap of variable size filled with air or water and (iii) cable sensor pressed at a borehole-wall.

2. Theoretical Background

Time domain reflectometry measures the propagation velocity of a broadband step voltage pulse (typical values: rise time $t_r \approx 70$ ps, sampling increment $\Delta t \approx 20$ ps) with a bandwidth of around 20 kHz to 25 GHz (Nyquist-frequency: $f_{max} = 0.5/\Delta t$). But due to the limitations of used connectors, type of the TDR device, coaxial cable type and length the effective bandwidth is reduced distinctly [1]. Under atmospheric conditions the velocity of this signal is a function of the frequency $v = 2/f$ and temperature T dependent effective relative complex permittivity $\epsilon_e(\omega; T) = \epsilon_e^0(\omega; T) - j\epsilon_e''(\omega; T)$ of the material through which it travels. The overall losses $\epsilon_e''(\omega; T) = \epsilon_d''(\omega; T) + \frac{\sigma_c(T)}{\omega\epsilon_0}$ of the material which have to be considered result from the dielectric losses $\epsilon_d''(\omega; T)$ and the conductive losses $\frac{\sigma_c(T)}{\omega\epsilon_0}$ due to a direct current electrical conductivity $\sigma_c(T)$. Here, ϵ_0 is the permittivity of free space and $j^2 = -1$ is the imaginary unit. It is often convenient to consider the analogy of propagation phase velocity and attenuation of an

electromagnetic plane wave (see [49], [6], [15], [41]):

$$v_p(\omega; T) = \frac{c}{\sqrt{2}} \sqrt{\frac{\epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)}{\epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)}} \quad (1)$$

$$\epsilon''_e(\omega; T) = \epsilon''_e(\omega; T) \sqrt{\frac{\epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)}{\epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)^2 + \epsilon''_e(\omega; T)}} \quad (2)$$

where $c = \frac{1}{\sqrt{\epsilon_0 \mu_0}}$ is the velocity of light and ϵ_0 the magnetic permeability of vacuum. Hence, any modulation of an electromagnetic wave in a real medium will propagate at a group velocity according to the Rayleigh equation ([11], [12]):

$$v_g = \frac{d\omega}{dk} = v_p \left(1 - \frac{f}{v_p} \frac{dv_p}{df} \right) \quad (3)$$

herein, k denotes the wave number. The at band cable of length l consists of three strip conductors embedded in a polyethylene band (see [20], [27] for details). The effective group or phase velocity of the signal v_p^0 in a perfect dielectric (pure real dielectric constant $\epsilon_r = \epsilon_r^2 = \text{const}$ without dispersion and conducting losses) surrounding the cable sensor is in principle only a crude approximation of the real material properties especially at frequencies $f < 1 \text{ GHz}$ and $f > 10 \text{ GHz}$ (c.f. Fig. 1)

$$v_p^0 = v_g = \frac{2l}{t} = \frac{c}{\sqrt{\epsilon_r}} \quad (4)$$

where t is two way travel time. Considering an analogous dispersion equation (4) is referred to as a high frequency approximation of phase velocity (Fig. 1). In contrast the high frequency attenuation approximation $\alpha_h(\omega; T)$ for real soils frequently used in ground penetrating radar applications works considerably well (c.f. [6], Fig. 1)

$$\alpha_h(\omega; T) = \frac{\omega \epsilon''_e(\omega; T) Z_0}{2 \epsilon''_e(\omega; T)} \quad (5)$$

with impedance $Z_0 = \frac{1}{c \epsilon_0}$ of vacuum. We now consider the soil as a four-phase medium composed of: air, quartz grain, water and clay. In the particular case of spatial TDR the surrounding medium in the direction of the band cable is described by a relative effective permittivity $\epsilon''_e(\mathbf{x}; \omega; T; p)$. It depends on position \mathbf{x} , angular frequency ω and contribution due to several relaxation processes via relaxation time $\tau_i(T; p)$ on absolute temperature T and pressure p ([22], [30])

$$\tau_i(T; p) = \frac{h}{k_B T} \exp \left(\frac{E_{a,i}(T; p)}{RT} \right) \quad (6)$$

Herein, h denotes the Planck-constant, k_B Boltzmann constant, τ_i the transmission coefficient, R gas constant and $E_{a,i}(T; p) = G_i(T; p) + T S_i(T; p)$ activation energy with free enthalpy $G_i(T; p)$ and activation entropy $S_i(T; p)$ of the i -th process ([22], [21]). Dielectric loss spectra of saturated and unsaturated soils very often show a marked deviation from simple Debye-behaviour ([17], [19], [22], [25]). Based on the theory

(right) Comparison of natural water with $\rho_b = 0.185 \text{ g/cm}^3$, a mikrosil quartz powder and SB 50/50-4 (see Tab. 1 and 3 below). The calculations were carried out under utilization of the measured dielectric permittivity.

of fractional time evolutions Hilfer [16] derived a Jonscher type function [23] for the complex frequency dependent dielectric permittivity of amorphous and glassy materials

$$\epsilon''_e(\omega; \alpha) = \epsilon'_1 = \frac{\epsilon''_i(\Gamma)}{(\omega^{\alpha-1})^2 + (\omega^{\alpha-1})^2} \quad (7)$$

with high frequency limit of permittivity ϵ'_1 , relaxation strength $\epsilon''_i(\Gamma)$ as a function of temperature, angular frequency ω and stretching exponents $0 < \alpha < 1$ similar to the familiar empirical Havriliak and Negami [14], Cole-Cole [3], Cole-Davidson [5] or Kohlrausch-Williamswatts ([26], [51]) dispersion and absorption functions. For the particular case $\alpha = 0$ and $\alpha = 1$ (7) transforms to the Debye model.

3. Material and Experiments

The complex effective dielectric permittivity ϵ''_e of saturated and unsaturated soils was examined in the frequency range 50 MHz-20 GHz at room temperature and atmospheric pressure with a HP 8720D-network analyser. This was performed using a combination

Figure 2. Schematic diagram of the experimental set-up for measuring the dielectric permittivity: (top) longitudinal section of the coaxial transmission line with an outer diameter of the inner conductor $d_i = 7 \text{ mm}$, an inner diameter of the outer conductor $d_o = 16 \text{ mm}$ and a length $l = 100 \text{ mm}$, (bottom) open-ended coaxial-line (HP 85070B).

of open-ended coaxial-line (HP 85070B) and coaxial transmission line technique (sample holder $(7 \times 16 \times 100) \text{ mm}^3$) (Fig. 2). The synthetic soil samples were incrementally wetted from air dry up to saturation with natural water and equilibrated 12h. From the prepared sample a subsample was taken with a retaining ring (height 100 mm, inner diameter 100 mm). The retaining ring was used as the sample holder for the HP 85070B probe. Care was taken to pack the soil in the transmission line to a homogeneous bulk density ρ_b and to a constant volume. After each dielectric measurement bulk density ρ_b as well as gravimetric water content w_g were determined. The measured complex S-parameter values S_{ij} were used to calculate complex dielectric permittivity with a commercial software (HP 85070/71C Materials Measurement Software) after calibration with open, short, and load standards.

Different natural and synthetic soils were investigated. Here, we present our results for synthetic soil SB 50/50. It is a mixture of 50 wt.% sand (grain size $< 2 \text{ mm}$) and 50 wt.% bentonite (Calcigel: 71 wt.% Ca-di-octahedral smectite, 9 wt.% illite/di-octahedral mica, 1 wt.% kaoline, 1 wt.% chlorite, 9 wt.% quartz, 5 wt.% feldspar, 2 wt.% calcite, 2 wt.%

dolomite).

Ca-di-octahedral smectites are clay minerals, i.e. they consist of individual crystallites the majority of which are $< 2 \mu\text{m}$ in largest dimension. The crystal structure of clays has been established from X-ray diffraction studies for almost all types of common clays. Smectite crystallites themselves are three-layer clay minerals. Individual clay layers consist of fused sheets of octahedra of Al^{3+} or Mg^{2+} oxides and tetrahedra of Si^{4+} oxides. Substitution of Al^{3+} , Mg^{2+} or Si^{4+} with lower valence ions results in an overall negative charge on the layers, which is then compensated by cationic species (counterions, in the current case Ca^{2+}) between clay layers (interlayers) ([29], Fig. 3).

Under increasing relative humidity the compensating ions become hydrated and the spacing between individual layers increases. While the detailed swelling characteristics of a smectite (interlayer spacing as a function of relative humidity) depends crucially on the charge of the clay layers (magnitude and localisation) and the nature of the compensating ion, in general, it occurs in three stages. Swelling begins in a step-wise manner (discrete layers of water formed in the interlayer, states referred to as monolayer/monohydrated, bilayer/bihydrated, etc.), becomes continuous thereafter and in the extreme a colloidal suspension of clay particles (< 10 aligned layers) is formed. Beyond the microscopic scale, aggregates of aligned clay layers form particles of the order of $10 \text{ nm} - 1000 \text{ nm}$ in size, with porosities on the meso- ($8 \text{ nm} - 60 \text{ nm}$) and macroscale ($> 60 \text{ nm}$) ([35] and citations in it). In Tab. 1 the physical and chemical

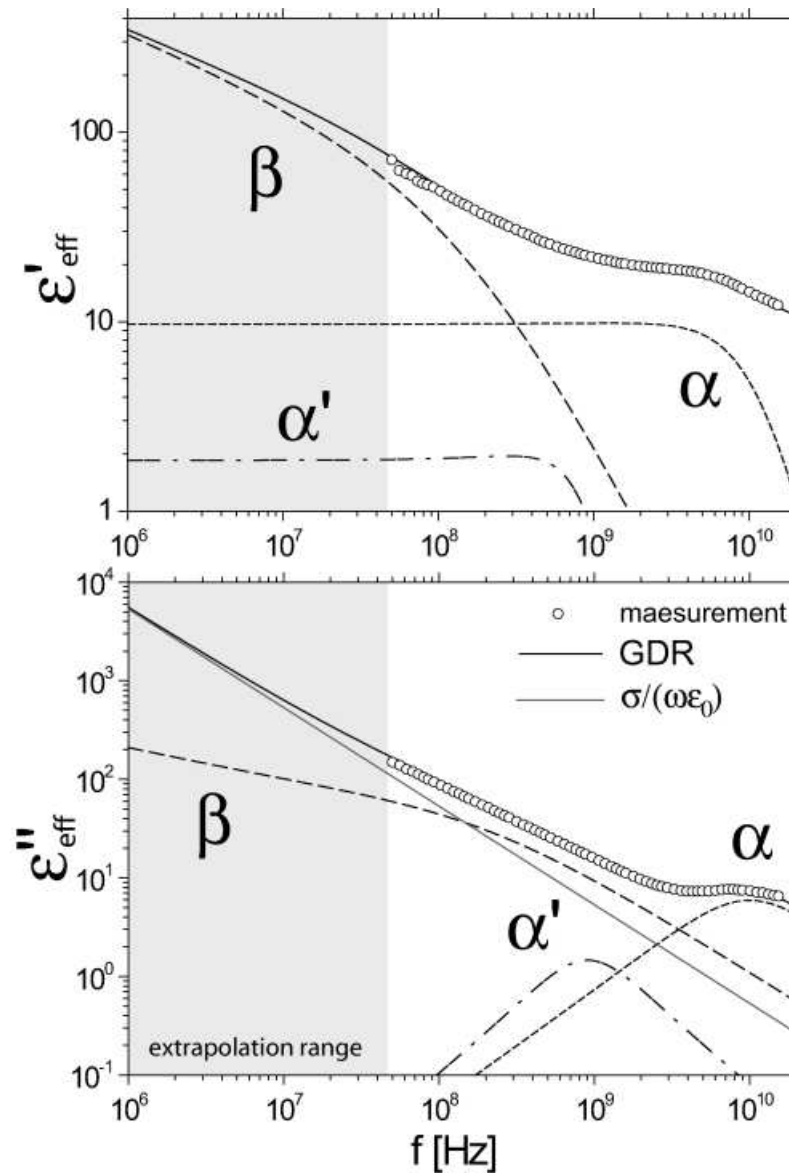

Figure 4. Complex relative dielectric permittivity $\epsilon_e^* = \epsilon_e' - j\epsilon_e''$ as a function of frequency of sand-bentonite mixture SB 50/50-4 with GDR-t under consideration of three relaxation processes: one primary process (main water relaxation) and two secondary (α' ; α)-processes due to clay-water-ion interactions (bound water relaxation and the Maxwell-Wagner effect). In this way it was possible to separate the single relaxation processes and to extrapolate the dielectric permittivity to 1 MHz.

properties of the used bentonite calcigel are summarized.

Three relaxation processes are assumed to act in the investigated frequency-temperature-pressure range: one primary process (main water relaxation) and two secondary (α' ; α)-processes due to clay-water-ion interactions (bound water relaxation and the Maxwell-Wagner effect, see Fig.4). The effective permittivity of a multiphase soil mixture ϵ_e^* can be determined by the complex relative permittivity of water ϵ_w^* , bound water ϵ_{bw}^* , the contribution due to clay-water-ion interaction ϵ_{clay}^* as well as the

Figure 5. Dispersion and absorption curve of sand-bentonite mixture (SB 50/50) for seven gravimetric water contents w_g and bulk densities ρ_b .

real and constant permittivity of quartz grain ϵ'_{sand} and air ([47], [37], [44], [48], [22], [21], [4]). The dielectric relaxation behaviour of each process is described by a fractional relaxation model according to (7) considering relaxation time distributions $H(\tau)$. This allows the complete spectrum to be treated as a function of water content w_g and bulk density ρ_b at constant temperature and pressure with the use of a generalized dielectric response (GDR, Fig. 4 and 5):

$$\epsilon'_{\text{eff}}(\omega) - \epsilon'_1 = \sum_{i=1}^N \frac{\epsilon_i}{(j\omega\tau_i)^{\alpha_i} + (j\omega\tau_i)^{\beta_i}} \quad j \frac{D.C}{\epsilon'_1 \epsilon_0} \quad (8)$$

A Shuffled Complex Evolution Metropolis (SCEM-UA) algorithm is used to find

best GDR-fitting parameters [5], Tab. 3). This algorithm is an adaptive evolutionary Monte Carlo Markov Chain method inspired by the SCE-UA global optimization algorithm of [7] and combines the strengths of the Metropolis algorithm [36], controlled random search [38], competitive evolution [18], and complex shuffling [7] to obtain an efficient estimate of the most optimal parameter set, and its underlying posterior distribution, within a single optimization run. The resulting relative error of each parameter is less than 3%.

The relaxation parameters obtained from GDR-fit are presented in Fig. 6. Relaxation strength τ_1 of each process and relative high frequency permittivity τ_1 depend on moisture content. Above a gravimetric water content of 30wt.% the τ_0 -process decrease and the τ_1 -process strongly increase. This suggests an increase of the primary τ_1 -relaxation at the expense of the bound water process τ_0 . In contrast at the highest saturation level of 0.66 at a porosity of 0.53 primary and low frequency τ_0 -process decrease. Relaxation time τ_1 and distribution parameter β_1 are nearly constant. An exception represents sample 50-0 which shows clear deviation from the general trend but because of the very low gravimetric water content of 0.6 wt%. Without swelling an increasing saturation reduces the gas-filled pore space, while the effective pore space available for the fluid becomes larger. This leads to the simple calibration models mentioned in the introduction to determine the volumetric water content with dielectric measurements. Due to the swelling of the clay minerals in the process of the hydration the distribution of immobile and effective pore space cannot be considered as constant. A

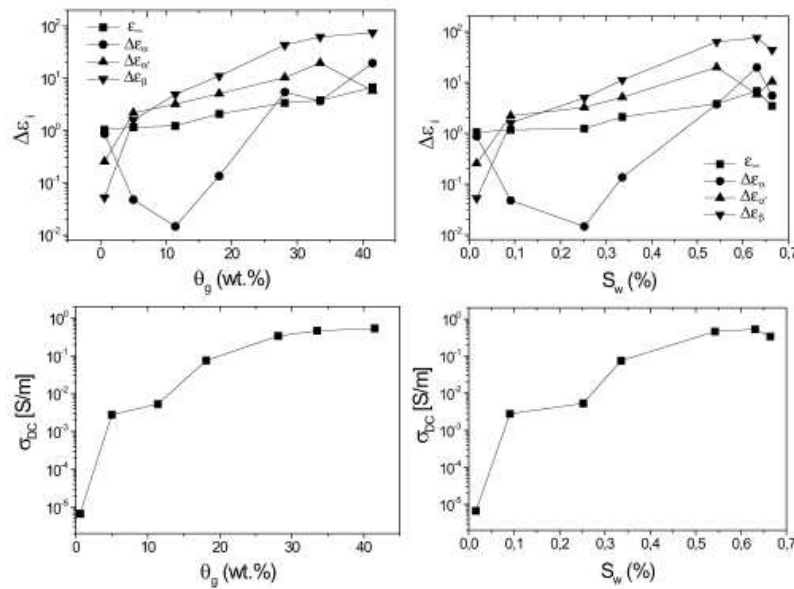

Figure 6. (top) Relaxation strength $\Delta\epsilon_i$ of the i -th process in comparison to the relative high frequency permittivity ϵ_∞ as a function (left) of gravimetric water content and (right) water saturation S_w . (bottom) Apparent direct current electrical conductivity σ_{dc} .

circumstance which complicate a careful realization of accurate measurements is the fact that a multitude of variables of the measurement conditions and the sample preparation essential determine the intensity of the swelling and the resulting change of the pore structure ([1]).

The results show the potential of the chosen approach but a detailed explanation of this complex behavior is beyond the scope of this paper. In general, there is a need of further systematic investigations by broadband dielectric spectroscopy of saturated and unsaturated soils under consideration of the swelling process and with an utilisation of microscopic modelling.

4. HFSS-Simulations

The transfer or scattering function $S_{ij}(!)$ of the at band cable section (Fig. 7) was simulated by finite element modelling (commercial software from Ansoft: High Frequency Structure Simulator-HFSSz) under certain conditions: (i) in direct contact to the surrounding material (air, water of various salinities, different synthetic and natural soils (sand-silt-clay mixtures)), (ii) with consideration of a defined gap of various size (total high 2 mm, 3 mm, 5 mm, 7 mm or 10 mm) filled with air or distilled water and (iii) cable sensor pressed at a borehole-wall.

In HFSS tangential element basis function interpolates field values from both nodal values at vertices and on edges. Surfaces of the structure (air-box) in the y - z and x - y z HFSS is a standard simulation package for electromagnetic design and optimization.

plane are radiation boundaries and the second-order radiation boundary condition is used

$$\frac{\partial \mathbf{E}_t}{\partial r} = -jk_0 \mathbf{E}_t - \frac{j}{k_0} \nabla_t (\nabla_t \cdot \mathbf{E}_t) + \frac{j}{k_0} \nabla_t (\nabla_t \cdot \mathbf{E}_t) \quad (9)$$

where \mathbf{E}_t is the component of the E-field that is tangential to the surface and k_0 is the free space phase constant. The second-order radiation boundary condition is an approximation of free space. The accuracy of the approximation depends on the distance between the boundary and the object from which the radiation emanates. For this reason a sensitivity analysis was carried out for a total height of the structure between 20 mm and 50 mm in dependence of the material properties. The influence of the boundary

Figure 7. Model geometry of (top) flat band cable surrounded by saturated and unsaturated soil with a gap filled with air or water and (bottom) cable sensor pressed at a borehole wall with air or soil as borehole filling.

layer for the simulation into air can be neglected for a distance from the cable sensor greater than 12 mm so a minimum height of 25 mm is used.

Surfaces in the x-z plane are wave ports. HFSS assumes that each wave port is connected to a semi-ininitely long waveguide that has the same cross-section and material properties as the port. When solving for the S-parameters, HFSS assumes that the structure is excited by the natural field patterns (modes) associated with these cross-sections. The 2D field solutions generated for each wave port serve as boundary conditions at those ports for the 3D problem. The final field solution computed must match the 2D field pattern at each port.

Figure 8. Electric field distribution @ 12.5GHz for the investigated at band cable surrounded by air, sand-bentonite mixture (SB 50/50-4) with $w_g = 28.14\text{wt.}\%$ and $\epsilon = 1.79\text{g}\cdot\text{cm}^{-3}$ as well as a defined 3mm air or water gap. (left) Cross section, (right) longitudinal section of middle conductor.

The simulation is performed with a $\lambda/3$ based adaptive mesh refinement at solution frequency of 1 MHz, 10 MHz, 0.1 GHz, 1 GHz and 12.5 GHz. Broadband complex S-Parameter are calculated with an interpolating sweep in frequency range 1 MHz – 12.5 GHz with extrapolation to DC. The electromagnetic field distribution, S-parameter and step response (200 ps rise time) of the structure were computed in reflection and transmission mode.

5. Discussion

The simulation adequately reproduces the spatial and temporal electrical and magnetic field distribution in comparison with 2D-FE investigations of [20] (Fig. 8). Fig. 9 represents reflection and transmission factor as well as the corresponding TDR waveform for the sand-bentonite mixture at various water contents and bulk densities in reflection and transmission mode. As a reference material the simulation results for the cable sensor surrounded by air are included. As expected, the appropriate resonances in the reflection coefficient S_{11} shift with rising water content to deeper frequencies and the attenuation increases. In time domain onset travel-time as well as rise time of the TDR

Figure 9. (left) Input return loss magnitude or reflection coefficient S_{11} and forward transmission or transmission coefficient S_{21} as well as (right) TDR-waveform in reflection and transmission mode for simulated at band cable structure, surrounded by air and sand-bentonite mixture of various water contents and bulk densities (see Tab. 3).

signals are analyzed. As is clearly recognizable in both reflection and transmission mode, onset time increase and rise time decrease with rising water content.

Qualitatively the numerical calculation shows that sensitivity characteristic of the cable sensor changes along the sensor in dependence of the dielectric relaxation behavior of the surrounding material (Fig. 8). The investigated high-lossy sand-bentonite mixture cause in dependence of increasing gravimetric water content w_g and bulk density ρ_b an increase of TDR signal rise time as well as a strong absorption of multiple reflections. This leads to a frequency dependent decrease of spatial resolution and penetration depth (sensitivity region around the sensor) along the at band cable and fixed maximum length of the moisture-sensor available for application.

Coupling problems caused by air or water gaps lead to dramatic travel time distortion even for very small gaps (Fig. 10). The air filled gap with a thickness of 0.25 mm on both sides of the cable sensor already leads to the drastic underestimation of water content of 36%. In contrast a drastic overestimation occurs in the case of a water filled gap for the same gap size. Further increasing gap size leads to a maximum in the characteristic (anomalous behavior) at a gap thicknesses of approximately 2.7 mm, whereby up to the complete filling of the structure with water the effective dielectric constant decrease and the rise time increase. An explanation of this effect and the consequences linked with it are however still pending and require further numerical and

experimental investigations. Moreover, with HFSS it is not possible to consider an exchange of material between air or water-filled gap and surrounding medium.

As a consequence the gap works as quasi waveguide, i.e. the influence of the surrounding medium is strongly reduced but changes in dielectric properties along the cable sensor are reproduced.

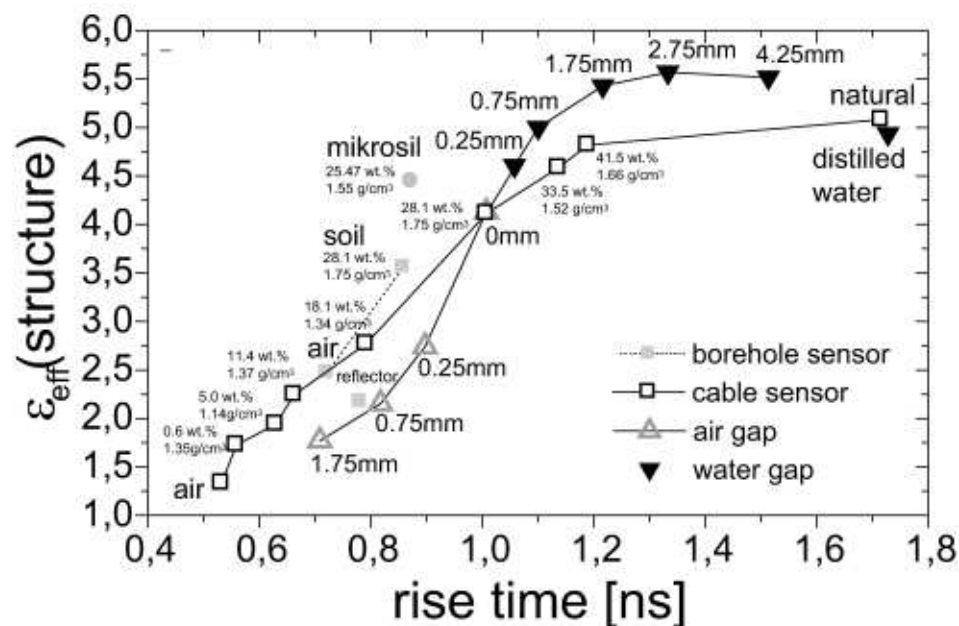

Figure 10. Real effective relative permittivity $\epsilon_{eff} = 2l/t_{onset}$ according to equation (4) plotted against TDR rise time t_{rise} (in reflection mode) for all sensor configurations and investigated cases.

6. Conclusion

In this study, the spatial sensor characteristics of a 6cm TDR at band cable section is simulated with finite element modelling in combination with dielectric spectroscopy.

For this purpose the dielectric relaxation behaviour of saturated and unsaturated soils is examined in the frequency range 50MHz-20GHz. The dielectric relaxation behaviour is described with the use of a generalized fractional relaxation model. With this approach the frequency depended dielectric permittivity is determined based on a parametrization of each relaxation processes as a function of water content and porosity. This enables a development of improved calibration strategies. However, there is a need of further systematic investigations by broadband dielectric spectroscopy of saturated and unsaturated soils under consideration of the swelling process and with an utilisation of microscopic modelling.

The three-dimensional numeric finite element simulation in HFSS provide an informative basis of the sensor characteristics under consideration of the frequency dependence of the measured complex dielectric permittivity. It is shown, that an air

or water gap between sensor and soil leads to dramatic under or overestimation of water content already for a gap thickness of 0.25 mm upper and below the cable sensor. Therefore, the application of the flat cable as a moisture sensor requires an accurate installation technique of cable-like elements (especially for long sensors). Moreover, the spatial sensitivity characteristics of the cable sensor changes along the sensor in dependence of the dielectric relaxation behavior of the surrounding material. For this reason, the precise determination of soil moisture profiles requires an improved TDR-waveform analysis strategy under consideration of the change of the sensitive area along the cable sensor.

A disadvantage of the used FEM with HFSS is the lack of consideration an exchange of material between air or water-filled gap and surrounding medium. In addition, to achieve sufficient accuracy the numerical simulations with HFSS requires a high degree of computational cost in terms of computational time and memory. Further, theoretical, numerical, and experimental investigations in conjunction with reconstruction algorithms have to point out to what extent the accuracy of water content and porosity profiles can be determined in strong dispersive, high lossy materials.
