## Abstract

We investigate random lattices where the connectivities are determined by the Voronoi construction, while the location of the points are the dynamic degrees of freedom. The Voronoi random lattices with an associated energy are immersed in a heat bath and investigated using a Monte Carlo simulation algorithm. In thermodynamic equilibrium we measure coordination number distributions and test the Aboav-Weaire and Lewis laws.

# 1 Introduction

Random lattices are a convenient way of approximating cellular network structures [1] and of discretizing space without introducing any kind of anisotropy [2]. The application of random lattices therefore covers a great variety of physical systems spanning from membrane and vesicle research, soap bubbles, sphere packings, kinetic growth models, large-scale structure of the universe to quantum field theory and two-dimensional quantum gravity [3, 4, 5, 6, 7, 8, 9]. It is therefore important to investigate and characterize the properties of random lattices and cellular structures. For cellular networks, e.g., grain mosaics, plants and foams relations such as the Aboav-Weaire and Lewis laws have, empirically, been found to provide good statistical descriptions. The Aboav-Weaire law states that the total number of neighbours of cells neighbouring an  $n$ -sided cell is linear in  $n$ , and has, recently, been derived from maximum entropy arguments [10]. However, in the case of a purely topological model it has been shown that there are small corrections to the linear relation [11]. The Lewis law, which states that the average area of  $n$ -sided cells is linear in  $n$ , has previously been shown to follow from maximal arbitrariness in the cellular distribution [12].

In the present paper we investigate two-dimensional random lattices where the location of the points are the dynamic degrees of freedom and the connectivities are at all times determined by the Voronoi construction. The purpose is twofold: First we introduce random lattices which will be in thermodynamic equilibrium and, secondly, this type of random lattices is then investigated in order to test statistical laws. The Voronoi construction or tessellation is defined as follows: For all points determine the associated cell consisting of the region of space nearer to the point than to any other point. Whenever two cells share an edge they are considered as neighbours and one draws a link between the two points associated to/located in the cells. In this way one obtains the triangulation of space that is called the Delaunay lattice. The Delaunay random lattice is dual to the Voronoi tessellation in the sense that points corresponds to cells, links to edges and triangles to the vertices of the Voronoi tessellation. The triangulation (tessellation) of space with  $N_P$  points (cells),

$N_L$  links (edges) and  $N_T$  triangles (vertices) are constrained by the Euler relation

$$N_P - N_L + N_T = \chi \quad (1)$$

where  $\chi$  is the Euler characteristic, which equals 2 for a graph with the topology of a sphere and 0 for a torus. Since  $3N_T = 2N_L$  always holds for a triangulation, one obtains  $N_T = 2N$  and  $N_L = 3N$  for  $N_P = N$  points on a torus. The connections of the lattice determine the connectivity matrix  $C_{ij}$  which is 1 if the points  $i$  and  $j$  are connected with a link and 0 otherwise. Voronoi structures have previously been the subject of interest in computer-simulation studies in two dimensions [13, 14, 15], where the Voronoi cells were used to determine nearest neighbours, and three dimensions [16]. Recently, the concept of Voronoi tessellations has been generalized in order to model equilibrated soap froths [4]. In the study in Ref. [15] the Voronoi tessellation was dynamically maintained during the simulation, and used to describe structural changes in the hard-disk model but the Voronoi construction was not used to determine the dynamics.

In the next section we define the dynamic random lattice. In Sec. 3 we present simulation results, and in Sec. 4 we investigate statistical laws. Finally, in section 5, we summarize and conclude.

## 2 Dynamic Random Lattices

In our work the Voronoi construction will dictate the dynamics since we are interested in the dynamic properties of random lattices. To the random lattice we therefore assign a thermodynamic energy functional of the general form

$$H = \sum_i E[n_i; a_i; \langle r_{ij} \rangle; C_{ij}] \quad (2)$$

where  $n_i$  is the coordination number of the point  $i$ ,  $a_i$  the area of Voronoi cell number  $i$ , and  $\langle r_{ij} \rangle$  the distance between the points  $i$  and  $j$ . The lattice is taken to be in equilibrium with a heat bath at temperature  $T = 1$  (we use units where Boltzmann's constant equals unity). Depending on the actual energy functional (2) assigned to the lattice very differently ordered states may appear at low temperatures. The form of the energy is not necessarily supposed to represent a description of a physical

system ; of course one can construct physically motivated actions as well but this is not our interest in this study.

At high temperatures the random lattice will be of Poissonian type [2, 13], i.e., the positions of the points are uncorrelated and uniformly distributed over the entire lattice. On the other hand, the action can be ingeniously chosen so that one obtains, at low temperatures, lattices with certain useful properties. In, e.g., the numerical growth of Diffusion-Limited Aggregation (DLA) clusters by solving the Laplace's equation on a random lattice,  $(\phi)_i = \sum_j^P C_{ij} (\phi_j - \phi_i) = \phi_{ij}$  [6], the convergence properties can be speeded up when the couplings  $\phi_i = \phi_{ij}$  are nearly constant. Such a lattice may be obtained by using an appropriate energy (2) and then equilibrating the random lattice in a Monte Carlo simulation.

With the standard Monte Carlo simulation techniques we have investigated Voronoi random lattices. Corresponding to the usual spin-1/2 for an Ising model the points defining the lattice are subject to random displacements. The new lattice is also determined by the Voronoi construction and the move is accepted with the Metropolis probability

$$P = \min(1; e^{-\beta \Delta H}) \quad (3)$$

where  $\Delta H$  is the increase in energy produced by the move. Provided the detailed balance condition is fulfilled the Monte Carlo dynamics will correctly describe a Voronoi random lattice in equilibrium with a heat bath at temperature  $T$ . By means of simulations one can measure thermodynamic quantities as well as testing statistical laws supposed to be valid for an equilibrated graph itself.

In Fig. 1 we show how a typical change of the lattice caused by the move of one point to a random nearby position looks like. [Another way to determine the new position is to restrict the point to, e.g., the Voronoi cell around the point] or to within a fixed distance,  $r$ , from the edges of the Voronoi cell; in this latter way non-overlapping particles of radius  $r$  (e.g., granular material [17]) can be simulated with a hard-disk interaction (similar to the model studied in Ref. [15]).] When the point  $P$  is moved as shown in Fig. 1 a link at the left is "broken" [a neighbour-losing process] and a link at the right is "formed" [a neighbour-gaining process] in order that the Voronoi construction is fulfilled for the random lattice with the point

in the new position. No matter how small the move of the point is taken to be, very complicated changes which can influence a large part of the lattice can take place. Even though it is impossible in advance to predict how profound the changes will be, it is always possible to view such complicated changes as a combination of neighbour-gaining and losing processes and in this way keep track of how the lattice gradually changes as a point is moved. When the new position is very close to the old position, simple changes, as shown in Fig. 1, are, however, most likely to take place.

We have studied a variety of different Hamiltonians, typically of the form  $H = J \sum_i F_i^2$ , with  $\sum_i F_i = \text{const}$ : (e.g.,  $F_i = n_i; i :: :$ ), where the sum is over the  $N$  points. A Hamiltonian of this kind with positive coupling constant  $J$  (which for matter of convenience is chosen to be unity) will favour a low-temperature phase where the quantities  $F_i$  are all equal due to the imposed constraint  $\sum_i F_i = \text{const}$ . The case of negative  $J$ , on the other hand, will have low-temperature states where the  $F_i$ 's are small at some points and large at others. Here we focus on the case where the energy depends on topological quantities and study the Hamiltonian

$$H = J \sum_{i=1}^N (n_i - 6)^2 \quad (4)$$

with positive and negative coupling constants; elsewhere results on other models, including couplings to Ising spins, will be given. One notices that, since a torus imposes the constraint  $\sum_i n_i = 6N$  on the coordination numbers (from Eq. (1)), the same dynamics is obtained with, e.g.,  $H = J \sum_i n_i^2$ ; in both cases the Hamiltonian (4) will favour that all  $n_i$  equal 6.

### 3 Simulations

In the Monte Carlo simulations we use a lattice with the topology of a torus, i.e., we impose periodic boundary conditions in both directions. The lattices we have simulated contained from  $N = 504$  to 1254 points. One Monte Carlo step (MCS) corresponds to one attempted move per particle. For each temperature we carried out 1000{2000 MCS to reach equilibrium and then measured data for another 10,000 MCS. Since we are interested in the properties of the random lattices themselves

we use point updates where the new position of a point is chosen within a box surrounding the old position. The size of this region is chosen so that the acceptance rate is about 50% in an intermediate temperature interval and not too small for low temperatures. As previously remarked, it is not possible in advance to know the amount of change that will take place when a point is moved. This implies that the updating algorithm is intrinsically non-parallelizable/non-vectorizable. Therefore, workstations (Sun Sparc 10's) have been used in our simulations of the dynamic random lattices. We have implemented different versions of the algorithm using both index tables in Fortran and dynamic pointer structures in the C programming language (see, e.g., Ref. [18]). Typically, we obtain an updating time for one point-moves of the order of 1 m sec (the time scales approximately linearly with the size of the box in which the points are allowed to be moved).

The positive coupling Hamiltonian (4) has as groundstate a lattice with the topology of a triangular lattice. In the phase space of positions of points one has in fact many groundstates, namely all distorted triangular lattices, since for the regular triangular lattice a point can be moved to a certain amount without leading to a link- $\phi$ . These short displacements of the points are not detected by the Hamiltonian (4) which measures only the coordinations of the random lattice. A low-temperature lattice ( $T = 0.1$ ) is shown in Fig. 2 (a), and in Fig. 2 (b) is shown the (dual) Voronoi tessellation for the same configuration of the points. One notices that the points do not seem to order in the low-temperature phase. Nevertheless, 96% of the points have  $n_i = 6$  for the lattice shown in Figs. 2 (a)-(b). Measurements of the energy as a function of temperature show that the energy is a steadily increasing function and the specific heat  $c(T) = V^{-2} T^{-2} (\langle E^2 \rangle - \langle E \rangle^2)$  determined by means of the fluctuation-dissipation theorem as the fluctuations in energy shows no sign of a peak except at zero temperature with trivial exponent. These findings are in agreement with the Mermin-Wagner theorem [19] which states that a two-dimensional continuous system cannot undergo an order-disorder phase transition at a finite temperature.

Starting from an almost regular triangular lattice at a low temperature and heating up the system one observes single localized link  $\phi$ ippings which create points

with 5 and 7 neighbours respectively, i.e., pairs of "defects". Such points typically merge after a few Monte Carlo steps but as the temperature is increased these defects start to break up and the lattice becomes more and more random until it, eventually, will end up as the Poissonian random lattice at infinite temperature. On the contrary, cooling the high-temperature lattice these defects merge (annihilate) and eventually the points with 6 neighbours "percolate" from one side of the system to the other. Due to the periodic boundary conditions some topological defects can be "frozen in" in the low-temperature "ordered" phase where, e.g., connections across a line have all been shifted by one or more units. Qualitatively this scenario resembles the unbinding of vortices typical of the Kosterlitz-Thouless transition of two-dimensional melting. One way of describing these low-temperature patterns is by identifying the characteristic "ABC-sublattice" ordering for a triangular lattice and to see if this order propagates all over the system (i.e., percolates); results of such an analysis will be described elsewhere.

The negative J Hamiltonian (4) will have as its groundstate a lattice where one point has all the other points as neighbours, since the energy (4) favours an uneven distribution of the number of neighbours. For low temperatures there will be many metastable disordered states one of which is shown in Figs. 2 (c)-(d). Accessing these states by simulated annealing we find that up to 80-90% of the points have  $n_i = 4$  and these points lie along (fluctuating) lines. Specifically, the lines tend to close in circular patterns with a many-neighbour point (e.g.,  $n_i > 60$ ) lying in the middle, cf. Figs. 2 (c)-(d). From Fig. 2 (c) one notices that the circular patterns are roughly of the same size. Due to the very low energy associated to these central points it is highly unlikely that once a circular pattern has emerged it will break up again. The system therefore freezes into a metastable state and high energy barriers must be overcome to get out (at high temperatures these patterns will not appear but for low temperatures one has to be aware of the possibility of ending up in a metastable state and not the true equilibrium state). We have measured the energy as a function of time. For high temperatures there is a fast relaxation to equilibrium but as the temperature is lowered to  $T_{\text{c}} \approx 11$  the system enters a new phase where the relaxation to equilibrium is very slow (possibly determined by a power-law behaviour) being

due to the many low temperature disordered metastable states in the system. In fact it is possible that in the low temperature regime the system always evolves towards the topologically unique groundstate given by all  $n_i = 4$  except one which has  $n = 2N$  but that the system's evolution becomes extremely slow like in a glass.

## 4 Statistical Laws

From the Euler relation (1) follows that the average coordination number of a graph on a torus is 6, i.e.,

$$\langle n \rangle = \sum_n n P_n = 6 \quad (5)$$

where  $P_n$  is the (normalized) probability,  $\sum_n P_n = 1$ , of finding a point with  $n$  neighbours (this result is true for a graph of arbitrary topology in the limit  $N \rightarrow \infty$ , since the Euler characteristic is a number of order unity). This probability density has been plotted for various temperatures in Fig. 3 for the two models studied. At low temperatures for the positive coupling model one notices a strongly peaked density at the value  $n = 6$  reminiscent of the topology of the triangular lattice. Remember, however, that the lattice does not have the regular structure of a triangular lattice and even at rather low temperatures already contains defects and irregularities (cf. Figs. 2 (a)–(b)). The variance (the energy per point)  $\sigma^2 = \langle (n - 6)^2 \rangle = \sum_n (n - 6)^2 P_n$  decreases as a function of temperature and approaches zero at low temperatures, where only points with 5, 6 and 7 neighbours are present.

In the negative coupling constant case Fig. 3 (b) shows that owing to the points with many neighbours (cf. Figs. 2 (c)–(d)) the  $P_n$  density is broader for low temperatures as compared to the case of positive  $J$ . As the temperature is lowered the variance  $\sigma^2$  increases from the Poissonian random lattice value  $\sigma^2 = 1.78$  (see, e.g., Ref. [13]) to  $\sigma^2 = 2.7$  at the temperature  $T = 11$ , where the circular patterns start to form. The occurrence of the very high  $n$  values makes  $\sigma^2$  increase even further as the temperature is decreased. From Fig. 2 (b) one notices the change in the overall form of  $P_n$  taking place at the transition temperature  $T = 11$ . The transition seems very sharp and it would be interesting to investigate if it is of first or second order.

We now turn our attention to the correlations present in the equilibrated random

lattices. Denoting by  $m(n)$  the average number of neighbours of the neighbours of a cell with  $n$  neighbours the Aboav-W eaire law states that (see, e.g, Ref. [1])

$$nm(n) = (6 - a)n + (6a + \alpha_2) \quad (6)$$

with  $a \approx 1$ , empirically. Note that by parametrizing the Aboav-W eaire law by  $a$  as done in Eq. (6) the sum rule  $\sum m(n)i = \sum n^2 i = \alpha_2 + 36$  is automatically fulfilled [1]. This law has recently been predicted from maximum entropy arguments [10], whereas the analytical solution of a topological model showed that the linear law is only approximately true [11]. For the Poissonian random lattice it is well established that the linear Aboav-W eaire law does only approximately hold [13, 20]. This has been explained by arguing that this particular random lattice is not fully equilibrated | it is young in the terminology of statistical crystallography and is space-filling by construction rather than through a constraint [20]. One may argue that the dynamic Voronoi random lattices also are space-filling by construction rather than by a constraint.

Independent of temperature we find from our Monte Carlo simulation results for the equilibrated random lattices that when plotting  $nm(n)$  against  $n$  the points generally tend to lie on slightly concave curves, as can be seen from Fig. 4(a); however, for an intermediate  $n$  interval a linear law with a slope  $\approx 5.3$  approximates the curves well. The positive coupling model at very low temperatures ( $T = 0.1$ ) is atypical since only points with 5, 6 and 7 neighbours are found. For such a random lattice with only a small number of isolated  $\backslash 5$ 's and  $\backslash 7$ 's one has that  $m(n) \approx 6$ , which would be exact for a triangular lattice. This leads to  $nm(n) \approx 6n$ , which is in accordance with the results in Fig. 4(a) for the temperature  $T = 0.1$ . Raising the temperature, points with lower and higher coordination numbers occur and the linear law is no longer a good description. Instead the points lie on a slightly bent curve (cf. Fig. 4(a)) which can be fitted numerically by, e.g., adding a term  $\propto \ln^2$  on the right hand side of Eq. (6) (cf. Ref. [13]).

Also in the negative coupling case a straight line provides a good approximation. For high  $n$  values ( $n_1 > 10$ ) there are large deviations from an approximate linear law and the  $nm(n)$  values drop drastically. Simulations on lattices with a larger number of points show that this is due to finite-size effects, i.e., by simulating even larger

systems the curves extend to higher  $n$  values before they drop. As the temperature is lowered the curve is shifted a little upwards but the overall form does not change (cf. Fig. 4 (b)). When the temperature becomes so low that the circular patterns start to develop we see large deviations from a linear relation with  $\ln(n)$  values up to more than 100 (not shown) but, as previously discussed, the random lattices are then difficult to fully equilibrate.

Another empirical law is Lewis' law which has been found to hold throughout the evolution of several two-dimensional cellular structures (see, e.g., Ref. [20]). Lewis' law states that the average area  $A_n$  of  $n$  sided cells is linearly related to  $n$  as

$$A_n = A [1 + (n - 6)] \quad (7)$$

Here  $A = A_{\text{tot}}/N$  is the average area of a cell belonging to a cellular network consisting of  $N$  cells (points) and with total area  $A_{\text{tot}}$ , and is an adjustable parameter. The linear relation (7) has been obtained from maximum entropy arguments with the constraint that the structure at all times is space-filling [12, 20]. The idea underlying these maximum entropy arguments is to maximize the entropy  $S = - \sum_n P_n \ln P_n$ , subject to the normalization constraint  $\sum_n P_n = 1$ , the topological constraint (5) and the space-filling constraint  $\sum_n P_n A_n = A$ . Furthermore, it was obtained that  $P_n = \frac{1}{3} \left(\frac{3}{4}\right)^{n-2}$  in the  $N \rightarrow \infty$  limit. Since our probability densities (cf. Fig. 3) clearly are not of the above exponential form, this means that there are other constraints present (according to the entropy based arguments, cf. Refs. [12, 20]). For our system an additional constraint is  $\sum_n P_n E_n = E(T)$ , where  $E_n = (n - 6)^2$  and  $E(T)$  is the thermodynamic energy per point, which is measured in the Monte Carlo simulation.

In Fig. 5 is shown the dependence of  $A_n$  on  $n$  for different temperatures for the two models (the average area  $A$  has been normalized to unity). One notices that Lewis' law provides a good description of the equilibrated Voronoi random lattices and since the random lattices can be regarded as space-filling, this is in accordance with the results in Refs. [12, 20]. For the negative coupling model one obtains

0.23 independent of temperature for  $T > 11$ , cf. Fig. 5 (b), and then, due to the circular patterns, large deviations (not shown) are seen where  $A_n$  for, e.g.,  $n = 7$  and 8 can become as large as 10. The deviations from a linear law for high  $n$  values

are due to the finite number of points and move to higher  $n$  values when larger systems are simulated. In the positive  $J$  case, cf. Fig. 5(a), the  $\chi$  value gradually changes from  $\approx 0.23$  for high temperatures to  $\approx 0.5$  for low temperatures with deviations from a linear law for high  $n$  values (and these deviations continue to exist for larger systems).

## 5 Conclusions

In the present paper we have investigated equilibrated random lattices with connectivities determined by the Voronoi construction. The random lattices have been studied using Monte Carlo simulations where an update consisted in moving a point to a new randomly chosen position and then accept the new configuration with a probability depending on the equilibrium distribution.

We have investigated the topological Hamiltonian (4) for both positive and negative couplings  $J$ . We found that for negative coupling constants the low temperature phase resembles a glass with many metastable states, while for positive couplings a transition like in two-dimensional melting might be expected.

Statistical laws (Aboav-Waire's and Lewis' laws) known to provide a good description of natural cellular structures have been tested for the Voronoi random lattices. We find that the linear Aboav-Waire law provides a good description of equilibrated random lattices (but the points tend to lie on slightly concave curves similar to what happens for the Poissonian random lattice), and the linear Lewis law is followed with a temperature-dependent slope.
