We discuss the low-temperature dynamics of magnetic ux lines in samples with a family of parallel twin planes. A current applied along the twin planes drives ux motion in the direction transverse to the planes and acts like an electric eld applied to one-dimensional carriers in disordered semiconductors. As in ux arrays with columnar pins, there is a regime where the dynamics is dominated by superkink excitations that correspond to M ott variable range hopping (VRH) of carriers. In one dimension, how ever, rare events, such as large regions void of twin planes, can impede VRH and dominate transport in samples that are su ciently long in the direction of ux motion. In short samples rare regions can be responsible for mesoscopic elects.

The static and dynamic properties of magnetic ux lines in copper-oxide superconductors are strongly affected by pinning by point, linear and planar disorder [1]. Linear correlated disorder in the form of columnar defects produced by bom bardm ent of the crystal with energetic heavy ions has been shown to greatly enhance pinning in both yttrium and thallium -based com pounds [2]. Twin boundaries are an example of planar disorder that is ubiquitous in superconducting Y B  $a_2$ C  $u_3$ O  $_7$  x and La<sub>2</sub>CuO<sub>4</sub>. Early decoration experiments indicated that the superconducting order parameter is suppressed at a twin boundary and the twin attracts the vortices [3]. Extensive investigations of twin-boundary pinning have been carried out by Kwok and coworkers [4,5]. These authors studied a variety of YBCO single crystal sam ples containing single fam ilies of parallel twins lying in planes spanned by the caxis, with spacings ranging from m icrons down to several hundred Angstroms. Transport experim ents [4] show clear evidence of strong tw inboundary pinning even in the ux liquid phase for external elds along the caxis and driving currents in the ab plane and parallel to the plane of the twins (resulting in a Lorentz force norm alto the twin planes). For this geometry the linear resistivity drops sharply at a characteristic tem perature where twin-boundary pinning sets in [4]. In addition, there is a sharp downward dip in the resistivity as a function of angle as the external eld is rotated through the c direction [5].

The static and dynam ic properties of ux-line assem blies in the presence of a random array of colum nar pins have been studied by mapping the physics of magnetic ux lines onto the problem of localization of quantum mechanical bosons in two dimensions [6]. At low tem peratures there is a \Bose glass" phase, with ux lines localized on colum nar pins, separated by a phase transition from an entangled ux liquid of delocalized lines. Transport in the Bose glass phase closely resembles the variable range hopping (VRH) of electrons in disordered sem iconductors in two dimensions [7].

In this paper we study ux-line dynam ics in the presence of a single fam ily of parallel twin boundaries lying in planes containing the c axis, for H k c. W e nd that due to the quasi-one-dimensional nature of vortex transport a new regime can arise at low currents where ux-line dynam ics is dominated by rare events, such as large regions voids of twin planes, that can be responsible for new mesoscopic phenomena.

At low tem peratures, when the average vortex spac-(  $_0=B$  ) exceeds the average distance d between ing a<sub>0</sub> twin planes, all ux lines are localized by the pinning potential in the direction norm alto the twins, progressively  $\setminus$  lling" the planar pins as the eld is increased. We only consider elds below B<sub>f</sub>  $_0=d^2$ , where the ux lines 11 the twins, and neglect any additional weak point disorder in the sam ple. W e focus on ux m otion transverse to the twin planes, which resembles the hopping of electrons in one-dimensional disordered superconductors. The current density in the usual hopping conductivity problem corresponds to the vortex velocity (i.e., voltage) and the electrical conductivity m apsonto the resistivity from vortex motion. Transport in this low temperature and eld regim e is dom inated by single-vortex dynam ics. F lux m otion is described in terms of therm ally activated jumps of the vortices over the relevant pinning energy barriers U(L;J), yielding a resistivity = E=J, [1]

(T) 
$$_{0}e^{U=T}$$
; (1)

where  $_0$  is a characteristic ux-ow resistivity. In the following we determ ine the barrier heights U (L;J) (Table 1) corresponding to various transport regimes and the boundaries between the di erent regimes in the (L;J) plane.

Our starting point is the model-free energy discussed in [6] for ux lines de ned by their trajectories  $fr_i(z)q$ as they traverse a sam ple of thickness L with a fam ily of parallel tw in boundaries parallel to the zx plane,

$$F_{(N)} = \sum_{i=1}^{N} F_i + \frac{1}{2} \sum_{i=j}^{N-2} V(jr_i(z) r_j(z))dz; \quad (2)$$

where V (r) is the intervortex interaction [8] and  $F_i$  is the single-ux line free energy,

$$F_{i} = \int_{0}^{2} dz \frac{\gamma_{1}}{2} \frac{dr_{i}(z)}{dz}^{2} + V_{D}(y_{i}(z)) : \qquad (3)$$

Here  $\sim_1$  is the tilt modulus ( $\sim_1$  = (M  $_2$  =M  $_z$ )  $_1$  <  $_1$ , with  $_1$  the line tension) and  $V_D$  (y) represents a z-and xindependent pinning potential [9]. At low tem peratures we model  $V_D$  (y) as an array of identical one-dimensional square potential wells of depth U<sub>0</sub>, width 2b<sub>0</sub> and average spacing  $d >> b_0$ , passing com pletely through the sam ple in the x and z directions and centered at uniform ly distributed random positions along the y axis.

As discussed in [6] and [10], many relevant results regarding the statistical mechanics of ux lines can be obtained from elementary quantum mechanics by mapping the vortex trajectories onto the in aginary time path integrals of two-dimensional particles in a static random potential  $V_{\rm D}$  (y). In this mapping  $k_{\rm B}$  T plays the role of h,  $\sim_1$  that of the mass of the ctitious quantum particle, L  $^1$ that of the particle's tem perature. If we assume that each

ux line spends m ost of its time near the attractive tw in planes, the dynamics of ux lines driven by a Lorentz force norm al to the twin planes can be described by a tight-binding model for one-dimensional bosons, where the lattice sites are the positions of the twin planes. Flux lines can \tunnel" between twins i and j separated by a distance dij at a rate given by the tunneling matrix ele-2U (T) e  $E_{ij}=T$  , where  $E_{ij}=T$ m ent t<sub>ij</sub> 2~1U (T)dij is the energy of a \kink" con guration connecting the two pins and U (T) is the e ective binding free energy per unit length of a ux line trapped near a twin plane. At low tem perature U (T )  $U_0$ . Therm all uctuations renorm alize U<sub>0</sub> above a crossover tem perature, as discussed in [10]. Them odeling of the dynam ics of two-dimensional bosons in terms of a tight binding model in one dimension can be understood as a result of vortex-vortex interactions which con ne each ux line within a \cage" of radius a<sub>0</sub> form ed by its neighbors. Each line can be viewed

as moving within a one-dimensional \channel" of width

a<sub>0</sub>. Another e ect of interactions is the energy cost for an additional ux line to be placed on an already lled twin boundary. This is incorporated into an energy cost V<sub>0</sub> for double occupancy of a site of the one-dimensional tight-binding lattice, which is estimated as  $V_0 = 4_0 d^2 = a_0^2$ for  $T < T d = b_0 [ln (a_0 = 2d)]^1$  and  $d < < a_0 < < a_b$ .

W e consider vortex transport in the presence of a driving current J? H parallel to the twin planes, i.e., J\$. The applied current exerts a Lorentz force J = per unit length on the vortices,  $f_L = \frac{0}{C} \hat{z}$   $J = \hat{y} f_L$  in the direction transverse to the twin planes. In the context of the analogy with boson quantum mechanics, this term represents a ctitious \electric eld"  $E = \frac{1}{c} \hat{z}$   $J = \hat{y} J = c$ acting on particles with \charge" 0. At low temperatures the critical current can be obtained by equating the Lorentz force to  $U_0=b_0$ , where  $b_0$ ab, ie.  $dU_0 = {}_0b_0$ . Renorm alization of  $J_c$  by therm al J<sub>c</sub> (0) uctuations have been discussed in [6].

If we neglect rare events, the energy barriers determ ining the resistivity of Eq. 1 can be estimated as the saddle-point free energy associated with the low -lying excitations from the ground state (where all the lines are localized on twins). The results are summarized in Table 1. The phase diagram in the (L;J) plane is controlled by the parameter = q()dU(T), where q()is the density of states for the most weakly bound ux  $H_{c1}$ )=4 is the chem ical potential lines and о**(**Н which xes the ux line density. The low-lying excitations that govern transport at low tem perature have been discussed before in the context of ux arrays pinned by columnar defects [6]. The only di erence here is in the exponent of the barrier associated with VRH, both in the linear and nonlinear regime. In the presence of lin- $(J=J)^{1=3}$ , while for planar defect ear defects U<sub>VRH</sub> the corresponding exponent is 1=2, as shown in Table 1.

The boundaries of the (L;J) phase diagrams (Figs. 1 and 2) have not been discussed before in detail. The line  $J = J_L (L)$  de nes the boundary in the (L; J) plane that separates the regions of linear (J <  $J_L$  (L)) and nonlinear  $(J_{D} > J_{L}(L))$  response, with  $J_{L} = CE_{k} = (_{0}Ld)$  and  $E_k = - 1U$  (T)d the energy of a kink connecting neighboring pins separated by d. In the therm odynam ic lim it  $J_L$  ! 0 and the IV characteristic is nonlinear at all currents. In samples of very small thickness L there is a linear resistivity at low currents due to the ow of uxline segments of length L and typical transverse width  $dL = w_k$ , with  $w_k = E_k = U$  the width of a kink Yrf connecting pins separated by d. W hen  $w_k < L < L_1$ , where  $L_1 = E_k =$  is the length below which dispersion from tunneling and interactions can be neglected, transport occurs via the hopping of vortices between nearest neighbor (nn) pinning sites. Here is the width of the impurity band arising from level dispersion from tunneling and intervortex interaction. The region of the phase diagram dom inated by nn hopping is only present if  $L_1 > w_k$ , or < U [11]. When  $L > L_1$  the dispersion of energies between di erent pinning sites makes motion by nearest neighbor hopping energetically unfavorable. Tunneling occurs instead via the form ation of \superkinks" that throw a vortex segment onto a spatially rem ote pin connecting states which optim ize the tunneling probability. Tunneling via superkinks is the analogue of M ott variable-range hopping of electrons between localized states in sem iconductors. The corresponding energy barriers  $U_{M \text{ ott}}$  is given in Table 1.

For J >  $\rm J_{L}$  (L) the resistivity is nonlinear. For  $\rm J_{1}$  <  $J < J_c$ , with  $J_1 = dJ$  (T) =  $_0d$ , ux motion occurs via therm ally activated \half-loop" con gurations of transverse width  $y_{h1}$  U=f<sub>L</sub>. For J < J<sub>1</sub> the size of the transverse displacem ent of the liberated vortex segm ent exceeds the average distance d between twin planes and transport occurs via VRH which generalizes the Mott mechanism to the nonlinear case. The characteristic current scales that governs VRH is  $J_0 = J_1 = .$  The VRH contribution to the resistivity dom inates that from half loop only if if  $U_{VRH} < U_{hl}$ , or  $J < J_2 = J_1$ . All current scales in Fig. 1 are much<sub>o</sub>sm aller than the pair breaking current  $J_{pb} = 4c_0 = (3^{5} \overline{3}_{0 ab})$ . The M ott and the rigid ow regimes are separated by a horizontal line above which  $U_{M \text{ ott}} < U_{rf}$ . Sim ilarly, the condition  $U_{VRH} = U_{hl}$ yields the vertical line separating the VRH and half-loop regions.

Transport in ux arrays with columnar pins is described by a phase diagrams similar to that of Fig. 1. The di erence for planar disorder is that transport is one dimensional in this case and rare uctuations in the spatial distribution of twins can impede VRH and dom inate ux-line dynamics. The vortex line can encounter a region where no favorable twins are available at the distance of the optim al jump. The vortex will then remain trapped in this region for a long time and the resistivity can be greatly suppressed. Rare uctuations can also occur in samples with columnarpins, but in that case they will dom inate transport only at extrem ely small elds, when the number of rare regions exceeds the number of vortices.

At a given tem perature and for applied currents below  $J_L$  , a vortex can jump from one twin plane to another at a distance y if the energy di erence per unit length between the initial and nal con guration is within a  $E_k y=Ld$ . A trap is then a region of conrange guration space (y; ) void of localized states within a spatial distance y and an energy band around the initial vortex state. A vortex that has entered such a trap or \break" will remain in the trap for a time  $t_w = t_0 \exp(2y=k)$ , where  $k = T = \frac{1}{2\gamma U}$  is the localization tion length and  $t_0$  a m icroscopic time scale. The probability of nding such a break is given by a Poisson distribution,  $P(y) = P_0(y) \exp[Ag(y)]$ , where  $P_0(y)$  is the concentration of localized states in the energy band 2Ag() and A 1 a num erical constant. ,Р<sub>0</sub>(у) The mean waiting time between jumps is

For L >>  $(T = E_k)^2 w_k = L$ , the integral can be evaluated at the saddle point, corresponding to the situation where the mean waiting time is controlled by \optim al breaks" of transverse width  $y_1$   $\downarrow$  L=L, with the result,  $\overline{t_w} = t_0^D \overline{L=L} e^{L=L}$ . The optim al breaks correspond to the longest trapping time and arem ost elective at preventing ux motion. The inverse of the trapping time determ ines the characteristic rate of jumps, yielding a linear resistivity,

bl 
$$_{0}$$
 (T=U<sub>M ott</sub>)e  $^{(U_{M ott}=T)^{2}}$ : (5)

For currents above  $J_L$  the typical energy per unit length available to a ux line for jumping a distance y is  $f_L y$ . Again, for  $J << (J_1 = ) (E_k = T)^2 = J$ the main contribution to the resistivity is from <code>\optim al</code> traps" of transverse size  $y_h = \frac{1}{2} (J = J)$ , with the result,

b 0 (
$$T = U_{VRH}$$
) e  $(U_{VRH} = T)^2$ : (6)

The contribution to the resistivity from tunneling a la M ott (both in the linear and nonlinear regim es) always dom inates that from hopping between rare optim altraps if both m echanisms of transport can occur. On the other hand, in one dimension if the sample is wide enough in the direction of ux-line m otion to contain optim altraps, tunneling a la M ott sim ply cannot take place because ux lines cannot get around the traps. These rare traps with large waiting times will then control transport. If W is the sam ple width in the y direction, the condition for having optim al traps of width  $y_{\rm lib}$  is P ( $y_{\rm lib}$ )W > 1.

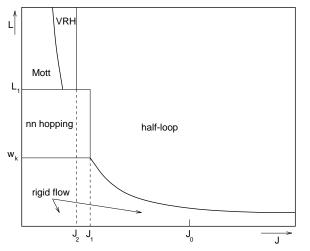

FIG.2. The (L;J) phase diagram for  $= g()dU < E_k=T$ .

Optimal traps will be present only if J >  $J_w = J = \ln (2W = l_P)$  for J >  $J_L$  and if  $L < L_w = L$  ln (2W =  $l_P$ ) for J <  $J_L$ .

A ux line can, however, escape a break by nucleating a half-loop, i.e., by tunneling directly into conduction band, if  $y_{h1} > y_b$ , or  $< E_k=T$ . The only e ect of rare uctuations in this case is of suppressing VRH for  $J > J_w$ , extending to lower currents the region where transport occurs via half-loop nucleation. For instance the right (high current) boundary of the VRH region in the phase diagram of Fig. 1 will be pushed down to  $J_w$  if  $J_w < J_2$ , or ln (2W =y<sub>T</sub>) > ( $E_k = T$ )<sup>2</sup>. Sim i-lar considerations apply to the linear response. Only if

>  $E_k=T$ , there will be a portion of the (J;L) plane where breaks dominate transport, as shown in Fig. 2. For YBCO, we estimate  $E_k$  1K A <sup>1</sup> d. Assuming

U= , the condition  $> E_k=T$  can only be satised at low elds (B < 1K G for d 200A). The sample will contain optim albreaks if W > 30A exp(J =J), with J 4  $10^5$ Amp/cm<sup>2</sup> at 80K.

If the sample is too short to contain optimal breaks, i.e., W P (y  $y_{1;b}$ ) < 1, the dynamics is controlled by the trap with the longest waiting time,  $t(y_f) \exp(y_f = l_2)$ , with  $y_f$  determined by the condition W P ( $y_f$ ) 1. The corresponding resistivity is  $_W = _0e^{y_f = l_2}$ . In this case the relevant physical quantity is the logarithm of the resistivity,

$$\ln \left( \begin{array}{c} W = 0 \right) = Y_{f} = \frac{1}{2}$$

$$\frac{U_{VRH}}{T} n \ln \frac{h^{2}W}{h} \frac{T}{U_{VRH}} \ln (2W = \frac{1}{2}) \quad : (7)$$

The leading dependence of Eq. 7 on current and tem perature is the same as that of the VRH contribution. Equation (7) also contains, however, logarithm ic terms that in su ciently short samples will give a random spread of values of the resistivity from sample to sample. These e ects have been discussed for sem iconductors [13]. In this case a more relevant physical quantity rather than the resistivity itself is the distribution of the logarithms of the resistivity over di erent samples. The expression (7) determines the position of the maximum of this distribution.
