## OVERLAP, DISORDER AND DIRECTED POLYMERS: A RENORMALIZATION GROUP APPROACH

Sutapa M ukherji

Institute of Physics, Bhubaneswar 751 005, India

The overlap of a d + 1 dimensional directed polymer of length t in a random medium is studied using a Renormalization G roup approach. In d > 2 it vanishes at  $T_c$  for t ! 1 as t where  $= \left[\frac{d}{3} \frac{1}{2d}\right]_z^d$  and z is the transverse spatial rescaling exponent. The same formula holds in d = 1 for any nite temperature and it agrees with previous numerical simulations at d = 1. Am ong other results we also determ ine the scaling exponent for mutual repulsion of two chains in the random medium.

O ne com m only studied quantity in random system s is the overlap of appropriate physical variables in di erent states as, for exam ple, the overlap of m agnetizations in two states for a spin glass system [1,2]. The distribution function for the overlap q, p(q), which, e.g., in a pure Ising system has two function peaks for the two possible low temperature ferrom agnetic states, has a nontrivial structure in the spin glass phase because of the broken ergodicity. Such nontriviality of the overlap distribution is the m ain characteristic for spin glass type system s. Notw ithstanding the importance of overlaps, very little is understood analytically about it.

Of late, a directed polymer in a random environment is taken to be the paradigm of disordered systems. This is because of the strong analogy in behavior with other random systems and spin glass  $\beta$ , and more so because of the availability of exact results through Bethe ansatz [4], use of various analytical and numerical methods like, nonlinear diemtial equation [5], transferm atrix [6{8] and other approaches. Even in this situation, the question of overlap remains a mind boggling issue [7,8]. In this paper, we implement a renormalization group (RG) approach to obtain the scaling behavior of the overlap. To our know ledge, no such analytical result for overlap is known for any other realistic random system.

The d+1 dimensional directed polymers are random walks stretched along a particular direction with uctuations in the transverse d dimensional space. These string like objects appear in various random systems of interface uctuations and pinning [4], crystal growth [5], spin glasses [9] etc. M ost of the recent work done on this problem attempt to understand the low temperature (strong disorder) phase which, as a matter of fact, is the only possible phase in 1+1 dimensions. The problem in 1+1 dimensions is almost settled with relevant exponents known exactly [10]. The two important exponents are and = 1 = z, which describe the free energy uctuation and transverse size as the length  $t \mid 1$ , namely f t =z and < x >t. For d = 1, z = 1=2 and z = 3=2, with z = 2. How ever, precise values of these exponents in higher dimensions and their exact dimensional dependences are not yet well understood mainly because of the lack of any perturbative xed point [11]. For high enough dimensions (d > 2) it is found that there is a phase transition [12,13] from the high tem perature (weak disorder) to the low tem perature phase (strong disorder). W hat happens at d = 2 is not clear [8,7], though the consensus seems to be against a phase transition [5,7]. W e m ention, in passing, that several exact results are known, especially in connection with such disorder induced phase transitions, if the random ness is in the interaction instead of the medium [14].

The high temperature phase of a directed polymer in a random potential in d > 2 is simple since there the quenched and annealed free energies are equal. The situation is more complex in the low temperature phase because of the nonzero overlap and the subsequent nonanalyticity of the free energy that supports the hypothesis of the coexistance of several pure states [9,3] – a phenom ena rem iniscent of spin glasses. Partial information regarding the therm al, geometrical properties and a few related distribution functions in the low temperature phase are available from M onte C arbo simulations, expansion m ethods and transfer m atrix techniques [13,8]. However, at present the overlap, especially near the critical point, seem s to elude these techniques. In this paper our main focus is at this transition temperature. Unlike the tree problem [15] which, in some way, corresponds to the m ean eld limit d ! 1, our result is true for nite dimensions. [See, e.g., Ref. [16] for the peculiarities of the Cayley tree problem .]

Sim ilar to the concept of the overlap of two di erent magnetization states [1], here in the DP picture, the overlap m eans the num ber of com m on spatial points visited by two di erent con qurations of the polymer. Introducing two di erent con qurations of a polymer is equivalent to starting with the original polymer with a replica. The overlap is then the average number of contacts of these two polymers (see below for a more precise de nition). The procedure for the evaluation of the overlap would be to introduce a new interaction that penalizes such contacts with coupling constant  $v_0$ . The overlap follows, as statistical mechanics prescribes, from the calculation of the appropriate derivative of the free energy of such an interacting system .

In the path integral representation the working ham iltonian for two interacting directed polym ers

$$H = \int_{0}^{Z^{t}} d \left[ \sum_{i=1,2}^{X} \frac{1}{2} \mathbf{x}_{i}^{2}(\cdot) + \frac{1}{2} \nabla (\mathbf{x}_{i}(\cdot); \cdot) + \frac{1}{2} \nabla_{0} (\mathbf{x}_{12}(\cdot)) \right]$$
(1)

where  $x_i(t)$  is the d dimensional spatial coordinate of the ith chain at the contour length  $t_{r_{i}}(t) = \frac{dx_{i}(t)}{dt}$ , and  $x_{12}$  is the relative separation of the two chains. The rst two terms represent the entropic uctuations of two free G aussian chains with as the bare line tension. V corresponds to the space and time dependent random potential seen by the two chains interacting at same t with function potential of strength  $v_{\rm c}=(2)$ . The signi cance of the peculiar factor  $\frac{1}{2}$  with the random potential and with the coupling constant  $v_0$  will be clear from discussions later. The random potential is taken to be uncorrelated, normally distributed [5] with

$$\overline{\mathbf{V}(\mathbf{x}; \mathbf{V}(\mathbf{y}; \mathbf{0}))} = 2 \quad (\mathbf{x} \quad \mathbf{y}) \quad (\mathbf{0})$$
(2)

where the overbar stands for the averaging over the disorder. The disorder is quenched so that the average of  $\ln W$ , where W is the appropriate partition function, is needed.

The overlap for the above system in the continuum limit can be precisely de ned as

$$q(t) = \frac{1}{t} \int_{0}^{2} d (x_{2}(t)):$$
(3)

It can be obtained from the relation  $q(t) = \frac{1}{t} \frac{df_2(v_0,t)}{dv_0} \dot{J}_{0=0}$  where  $f_2(v_0;t)$  is the free energy for the Ham iltonian in Eq.1. A scaling form

$$f_{2}(v_{0};t) = t^{=z}f(v_{0}t^{=z})$$
(4)

is expected with determining the crossover exponent. This implies  $q = t Q (v_0 t^{-z})$  where

$$= ( z)=z$$
 (5)

This particular problem in a discrete version at d = 1 has been studied by M ezard numerically in [3]. His simulation results are consistent with = 1=z = 2=3, = 1=2, and =z = 2=3. A corollary is that the behavior of one chain remains una ected by the presence of the other. This need not be surprising because the \screening" type e ects in ordinary self and mutually avoiding polymers are nite density phenomena. Since at d = 1

z = 0, one obtains  $q(v_0;t) = q(v_0t)^{-z}$ . One of our aim s is to determ ine .

Here we use the continuum formulation and map the problem to a KPZ type nonlinear di erential equation for the free energy [5,17]. A dynam ic renormalization group approach, a la Ref. [17], following a perturbative calculation in a Fourier conjugate space, is developed to study this equation. In the process, we obtain the scaling exponent for the interaction and establish that in any arbitrary dimensions and z remain the same as those of the single chain problem, as one would expect, even in the presence of the interaction. A series for the renormalized coupling constant can be identified by collecting the appropriate terms from the perturbative series. The recursion relation for the coupling constant, found after the use of the momentum shell technique, manifests the scaling form of the mutual interaction and the overlap. The exponents obtained through this process are for the critical point T<sub>c</sub> for d > 2 but for the nite temperature phase for d = 1. An appeal to nite size scaling then enables us to extend the result to T  $\notin$  T<sub>c</sub> for d > 2.

We consider two chains which are tied at one end (t = 0) at the origin of the d dimensional space and extended up to  $x_1$  and  $x_2$  at length t. The partition function W  $(x_1;x_2;t)$ , which is basically a sum of the Boltzm ann weights of all con gurations of two such chains can be written in the path integral form as

$$W (\mathbf{x}_{1};\mathbf{x}_{2};t) = \int_{(0;0;0)}^{Z} D \mathbf{x}_{1}^{0} D \mathbf{x}_{2}^{0} \exp[H];$$
(6)

where  ${}^{R}$  D  $x_{1}^{0}$  D  $x_{2}^{0}$  stands for all possible paths of the two polymers and H is given by Eq. 1. This implies that the partition function satis es a Schrödinger type equation written suppressing the argument of W

$$\frac{\partial}{\partial t} W = 4 \sum_{i=1;2}^{2} r_{i}^{2} + \frac{3}{2} g_{0} (x_{1}; x_{2}; t)^{5} W;$$
(7)

where  $g_0(x_1;x_2;t) = V(x_1;t) + V(x_2;t) + v_0(x_{12})$  appear as the potential.

Our approach starts with another version of the above equation for the free energy  $h(x_1;x_2;t) = (2 = ) \ln W(x_1;x_2;t)$  which satis es, again suppressing the arguments,

$$\frac{e}{et}h = \sum_{i=1,2}^{X} [r_i^2 h + \frac{1}{2} (r_i h)^2] + g_0:$$
(8)

The impressive feature of this equation is that the parameter , which was previously controlling the random potential and the mutual interaction between the chains in the original ham iltonian in Eq.1, now appears only with the nonlinear term. Eq.8 can be decoupled when there is no mutual interaction between the chains and such a decoupled equation can be solved exactly when = 0 [18]. One can then make a small perturbation in the nonlinearity (i.e. in which is electively equivalent to introducing a small disorder into the problem. The recursion relation for  $v_0$ , obtained after perturbation in the nonlinearity , gives the in uence of disorder on  $v_0$ .

A glance at Eq.8 shows that under the transform ation  $x \mid b x$  and  $t \mid b^2 t$  the parameters of the equation change as

$$(;;v_0)! (b^{z^2}; b^{+z^2}; b^{z^d}, v_0):$$
 (9)

Therefore in the absence of the nonlinearity i.e when = 0,  $z = z_0 = 2$  and = 2 d keep

and  $v_0$  invariant. This scaling furtherm one ensures the speciality of  $d = d_c = 2$  since for  $d < d_c$  a small amount of nonlinearity becomes relevant with the growth of the length scale. Such speciality of  $d_c$  is rejected later in the perturbative series. At this level one indicates the necessity of going beyond the simple scaling analysis to carry out the RG analysis since the scaling dimension of  $v_0$ , z d, vanishes at d = 1, while numerically it is found to be 1 [3].

The form al solution of Eq.8 in (K ;k;!) space, Fourier conjugate to  $(x_1;x_2;t)$ , is given by

$$h (K;k;!) = G_{0} (K;k;!) g_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;!)$$

$$R = 2 G_{0} (K;k;!) = 2 G_{0} (K;k;k;!) = 2 G_{0} (K;k;k;k;!) = 2 G_{0} (K;k;k;!) = 2 G_{0} (K;k;k;k;!) = 2 G_{0} (K;k;k;$$

where  $G_0(K;k;!) = ((K^2 + k^2))^1$  represents the bare propagator and  $\frac{R}{p_{PG}} = \frac{dp dq}{2} \frac{dp dq}{(2)^{2d}}$ . The fact that the random potential and the interaction are in the same footing in the above equation is now utilised in de ning the elective propagator G(K;k;!) and the elective coupling constant v as

$$h(K;k;!) = G(K;k;!)[V(K;!) (k) + V(k;!) (K) + v (K + k) (!)];$$
(11)

Note that such a restriction on m om enta is in posed autom atically by the RHS of Eq.10.

Now we are in a position to initiate the perturbative series, the terms of which after disorder averaging leads to \closed loop diagram s". [See, e.g., Ref. [17]]. Here we shall consider terms upto 0 ( $^2$ ) and 0 ( $v_0$ ). Collecting the appropriate terms from the perturbative series for the renormalized propagator satisfying either K = 0 or k = 0, one obtains a series identical to the renormalized propagator for a single chain in a random medium [5,17]. It becomes evident from the series that there is no contribution at 0 () since such terms either donot have any loop or even if they do, they contribute to 0 ( $v_0^2$ ), a higher order term which we are not considering here. For convenience, we cite the series obtained for a single chain propagator with momentum variable K

$$G (K;k;!) = G_{0} (K;k;!) + C (=2)^{2} G_{0}^{2} (K;k;!) (2) \Big|_{q;}^{K} q (K q) q K$$

$$G_{0} (K q;k;!) G_{0} (q;0;) G_{0} (q;0;) \qquad (12)$$

ъ

where C = 4 counts all the possible ways of noise contraction and k = 0 in this case. The term swhich contribute to the renorm alization of the vertex follow the constraint K + k = 0. One can write down the series for vG (K; K;0) to obtain an equation in which the vertex and the propagator G (K; K;0) renorm alization take place in a combined fashion and interestingly can also be isolated. To O (<sup>2</sup>) the series for the renorm alized propagator G (K; K;0) is same as Eq.12 with C = 8 and k = -K and v is given by the series

$$v = v_0 + 8\left(\frac{1}{2}\right)^2 (2v_0) \Big|_{q;}^{R} (q (K q))^3 G_0 (q; K; )G_0 (K q; 0; )$$

$$G_0 (q; q; 0) G_0 (0; q K; ):$$
(13)

In a digram m atic representation the second term on the RHS of this equation would correspond to an exchange type diagram. At the face value, the series of G (K; K;0) does not

resemble the series for the single chain propagator G(K;0;!), but it is easy to show that there is no change in the renormalization of the line tension from that of Ref. [5] in the long wavelength limit. This, furthermore, con rms that in any arbitrary dimensions, so far as the free energy, lateral extension are concerned, exponents do not change even after the inclusion of the mutual interaction.

The second term of Eq.13 involves a momentum integration with an upper cuto which indicates the resolution up to which the system is probed. To study the variation of v with length scale, we execute an RG procedure consisting of two steps (i) an integration over the momentum shell between the momenta and exp (1) and (ii) the momentum rescaling k ! k exp (1) which restores the upper cuto as before. Now after carrying out the rst step and the integration over we obtain an elective coupling constant (in the long wavelength limit) dilering from  $v_0$  by a term  $K_d^2v_0$  l=2. Here  $K_d = \frac{S_d}{(2)^d}$  with  $S_d$  as the surface area of the unit d dimensional sphere and  $2 = \frac{2}{3}$  is dimensionless. This additional term is the uctuation contribution of the disorder and crucial for the RG analysis. A little manipulation after the rescaling (step (ii)) produces the recursion relation

$$\frac{dv}{dl} = (z \qquad d)v + \frac{{}^{2}v K_{d}}{2}; \qquad (14)$$

with  $v = v_0$  when l = 0. The recursion for is quoted below from Ref. [5]

$$\frac{d}{dl} = \frac{2}{2} \frac{d}{dl} + K_{d} \frac{(2d-3)}{4d}^{3}$$
(15)

which has a xed point =  $[2d(2 \ d)=((3 \ 2d)K_d)]^{1=2}$ . At d=1 it is a stable xed point which shows that the phase is in uenced by the disorder at all tem peratures. There is no physical xed point for 1.5 < d < 2. The nontrivial xed point becomes unstable for d > 2. From the ow, one concludes that this unstable xed point corresponds to a critical point that seperates the two phases dominated by the entropy (high tem perature phase) or by the disorder (low tem perature phase). The situation at d = 2 is more complicated since disorder is marginally relevent [17,19]. Using the relation + z = 2, which is a consequence of Galelian invariance, and = we not from Eq.14

$$= (2 + d 2z) + d(d 2) = (3 2d):$$
(16)

At d = 1 exact values z = 3=2 and z = 1=2 yield the scaled variable as  $vt^{2=3}$ . The rem arkable feature is that in Eq.14 the term z d which originates from the simple scaling analysis of Eq.9, vanishes at d = 1 and the entire t dependence of the scaled variable com es only from the uctuation part. The scaling exponent of v m atches with the num erical prediction of M ezard at d = 1 [3]. Now, using the exponent , Eq.16 we nd

$$= d(d \quad 1) = [z(3 \quad 2d)]$$
(17)

Going back to the original problem of a single DP, the overlap is obtained by setting  $v_0 = 0$ . We therefore obtain

where, as mentioned before, this is the overlap in the low tem perature phase for d < 1.5 but at the critical point for d > 2. The exponent vanishes for d = 1, as has been found in Ref. [3]. Since < 0 for d > 2, the overlap disappears at the transition tem perature when the therm odynam ic lim it is approached - as one should expect.

We extend our  $T = T_c$  result to the critical region by invoking a nite size scaling hypothesis, [20]  $q = {}^{1}Q$  (t= ) where is the longitudinal (parallel to t) correlation length and jT  $T_c$  j near the critical point. Comparing with Eq.18, we nd  $_{1} =$ , so that, in the therm odynam ic lim it

as T !  $T_c$ . Unfortunately the value of is still not known with condence [7,8].

It is possible to explain the e ect of random environm ent m ore physically. In the situation where the disorder dom inates the physics, the chain is swollen to take advantage of the occasional traps that lower the energy. The loss in the entropy is o set by the gain in the energy, yielding > 1=2. In this scenario, it is therefore expected that the repulsion with another chain will have no signi cant e ect. Hence to the leading order,  $v_0$  is not to have any e ect on the renormalization of the properties of the polymers. However, with two chains there will be a certain amount of overlap in their attempts to take the advantage of the same traps. On a bigger scale, such closely spaced traps would appear as an inetraction between the chains. This leads to the renormalization of  $v_0$  changing its scaling exponent.

In sum mary, we have shown through one loop RG analysis that the behavior of a single chain in the random medium remains una ected even if we introduce another chain interacting with it through a short-range repulsive interaction. At d = 1 our results show a nite overlap at all temperatures indicating a strong coupling phase and the exponents match exactly with M ezard's numerical simulations. It may not be surprising that the 1 loop result gives exact results in 1 dimension, because it is known to happen for all the exponents for the d = 1 DP problem. This is mainly a consequence of G alelian invariance and uctuation-dissipation theorem. In higher dimensions (d > 2), we evaluated the scaling exponent of the overlap at T =  $T_c$ . By using a nite size scaling ansatz, we thereafter predict the temperature dependence of the overlap as T !  $T_c$ .

I thank S.M. Bhattacharjee for fruitful discussions and comments on the manuscript. I also thank D.D har for several suggestions.
