Abstract

The transition in random ber networks from two-dimensional to three-dimensional planar structure driven by increasing coverage (total ber length per unit area) is studied with a deposition model. At low coverage the network geometry depends on the scale-free product of ber length and coverage while at high coverage it depends on a scale-free combination of exibility, width and thickness of the bers. With increasing coverage the roughness of the free surface decouples from the substrate, faster when bers are stiller. In the high coverage region roughness decreases exponentially with increasing ber exibility.

PACS numbers: 81.30D x, 81.15Lm, 64.60-i

The mechanical and structural properties of two-dimensional random systems have recently been investigated intensively using computational and theoretical methods [1,2]. However, experimental studies are still few in numbers as suitable model systems seem to be lacking. Planar materials with random brous structure, such as polymer lms, short-ber composites, paper and nonwovens, provide promising possibilities for experimental work [3], in addition to their intrinsic technological interest. Fibers in real materials, such as paper, are much longer than the sheet is thick so that the in-plane alignment of bers is over 90% [4]. The structure is therefore planar, or "layered" (but without well-de ned layers), and the mechanical properties are essentially those of a two-dimensional system. The statistical geometry of strictly two-dimensional random ber networks is known quite well [5], but not the geometry of planar ber networks. A nalytical models [6, 7] have so far not dealt properly with the bonding of bers that are not located in adjacent "layers".

In this Letter we employ a simple computer simulation model to study how the geometry of a random network of exible bers forms during the build-up or sedimentation on a two-dimensional substrate ("growth in 2+1 D"). If coverage (i.e. the total ber length per unit area) is bw, the ber networks is almost two-dimensional and the inplane mechanical properties are governed by coverage. At high coverage, instead, the in-plane properties depend on the three-dimensional "bulk" density. However, in both cases the intrinsic property is the average number of connections (inter-ber bonds) per unit ber length or "coordination number" [8]. This in turn depends on the dimensions and exibility of bers. We concentrate on the coverage-driven transition from 2D to 3D network geometry with increasing coverage and on the corresponding change in the surface roughness [9]. Our results show the connection between the strictly two-dimensional random ber networks and their planar three-dimensional real-world counterparts, and thereby allow the comparison of future experiments with theoretical or numerical studies [10, 11, 12].

W e start with a two-dimensional square lattice of linear size L = 10 :::1000. The size L a ects properties only close to the percolation threshold and, for surface roughness, at very high coverages. Fiber length l_f is an odd integer multiple of the lattice constant (= 1), ber width and thickness are xed, $w_f = t_f = 1$, and emphasis is given to

 l_f 1 characteristic of bers [13]. Fibers are aligned at random [14] in the two principal directions and the centers of mass are located, again at random, over cell centers. Hence local coverage c (the total ber length per cell) has an integer value. Bending exibility T_f of bers is de ned by limiting the change in the vertical elevation of a ber from one lattice cell to the next to T_f (Fig. 1). A high T_f gives a dense network, a low T_f a sparse one. The so-called wet ber exibility [15] (W F F) of paper-making bers is related to T_f through $T_f = [C w_f W F F]^{3-4}$ where the constant C depends on experimental details.

D uring the buildup, bers are placed down independently, one after another, as if they were sedimenting from a dilute suspension. Each ber is kept straight and parallel to the substrate until it makes the rst contact with the underlying network. Thereafter the ber is deformed so as to lie as low as possible -but not below the substrate -while still obeying the de ection constraint T_f . Periodic boundary conditions are applied except in the percolation study. The discretization of network structure should not a ect generic properties. The cumulative build-up of the network is a more serious sim plication as it does not distinguish between densi cation mechanisms such as hydrodynamic drag forces and pressing of a ltrated berm at. However, the nite width of real bers in plies that they tend to follow a staircase pattern like that given by the model (cf. Fig. 1). The construction also leads to two-sided surface properties, but here only the free top surface is studied.

The model networks are characterized as follows. Local thickness t is the distance from the free top surface to substrate. Thus the mean thickness t includes the voids between the network and substrate. However, in calculating density these voids are subtracted away and so < 1 counts only for the voids within the sheet. This can be considered as the "true" density, one that is independent of surface roughness. A "coarse-grained" or "apparent" density is also employed to minic the nite in-plane resolution of realm easurements. In this case the system is rst divided into subgroups of 10 by 10 cells (the size being arbitrary) and the largest value $t = t_g$ is determined for each subgroup. The "apparent" density is then given by $g = c=t_g$ where c and t_g are the mean values of c and t_g . Finally, the coordination number n is de ned as the average bonded surface area of a ber, divided by $2l_f w_f$ [8]. At low mean coverage c the mechanical properties of a planar network should be controlled by c g where c_c is the percolation threshold [16, 17] form echanical connectivity. We determ ined c_c numerically using the following rules: 1) the network is connected when there exists a cluster of bers that is connected to at least one cell on two opposite boundaries of the system; 2) two cells are connected by a ber if the ber covers the both sites; and 3) two bers covering a cell are connected, if the top surface of the lower ber is in contact with the bottom surface of the upper ber. The threshold c_c is then equivalent to the bond percolation density of the dual lattice for bonds of length l_f 1. Thus an overall g 1=(l_f 1) behavior is expected. On the other hand, if the network had continuous spatial symmetry and the bers had zero width and in nite exibility, then the percolation density would be given by $c_c = 5:71=l_f$ [18].

The computed percolation threshold c_c is shown in Fig.2 for the lattice size L = 200. With long bers (lf 20) the threshold is ç 8=(⊒ 1) when T_f ! 1, which is slightly larger than with continuous sym metry. With short bers the non-zero width w_f low ers the asymptotic value so that $c_c = 6 = (\frac{1}{4} = 1)$ when $\frac{1}{4} = 5$. The asymptotic values at T_f ! 1 are independent of L, increasing L up to 800 revealed no deviation from the behavior shown in Fig. 2. A random walk argument suggests that in the opposite lim it ofT_f ! 0 the radius r of a cluster with N bers is r 1 N and therefore the thickness $\sharp (L=l_f)^2$. Thus the network becomes three-dimensional of a percolating cluster is and c_c very large and dependent on l_f and L. The non-smooth small- T_f behavior of c_c seen in Fig. 2 when $l_f = 5$ is reproducible and hence probably an artefact related to the fact that connectivity bene ts from rational values of T_f. Since the maximum vertical de ection per unit length of a ber is T_f, crossover between the exible ber and sti ber behaviors should occur at T_f $t_f = l_f$; our data suggests that this occurs at T_f 4=1.

W hen coverage c increases, coordination number n increases too and eventually becomes a constant, see Fig. 3. In the high-coverage region n is independent of l_f . In contrast to n, density decreases with increasing coverage because at c! 0 there are no intra-sheet voids. An order of magnitude higher coverage than with n is needed before "bulk" values of , independent of c, are obtained. The di erence is especially clear with sti bers. As n should be the main factor controlling the in-plane mechanical properties of the network, it follows that these become hom ogeneous, independent of coverage, at much lower coverages than density does.

The length of a ber l_f a ects the above results at low coverages, c g. For example, at the percolation threshold and with large T_f the number of inter- ber bonds per ber, given by $2n l_f$ is 7:1;6:3 and 4:7 for $l_f = 21$;11 and 5. However, at higher coverages the three-dimensional network structure should be controlled by the scale-free combination $w_f T_f = t_f$. This can be rationalized by observing that each ber on the surface of the network prevents new bers from making contact with others on $(w_f + l_f)t_f = T_f$ $l_f = T_f$ sites (on the average) when $l_f w_f$, while bonding with the ber in question is possible in $w_f l_f$ cells. Measured values of the wet ber exibility [15] and known dimensions of papermaking bers yield $w_f T_f = t_f = 0.5$ 0:7.

C coordination number n is tedious to measure directly and therefore density is sometimes used to estimate it. Indeed, Fig. 4 shows that if c is held constant and T_f is varied, then n is roughly proportional to and $_g$, as long as 0.6 and c is not too low. For example, in ordinary paper = 0.2 0.5 so that the linear behavior should be valid. The reproducible discontinuities at n 0.8 and 0.9 (corresponding to $T_f = 2$ and 4) are probably again artefacts of the discrete m odel. It is interesting to note that the slope dn=d 1.2 with $\frac{1}{2}$ 10 and approaches unity only for short bers. The slope depends slightly on coverage and thus density usually cannot be used to compare coordination numbers if coverage varies.

The two-dimensional projection of the network obeys Poisson distribution [5] and therefore the standard deviation of local coverage should be $_{\rm c} = {}^{\rm p}\bar{\rm c}$. Our simulations follow this relationship very accurately. The at substrate a ects the network structure at small c but at su ciently high c the structure is truly three-dimensional, independent of c. Then, for example, the standard deviation of the number of pores per cell p becomes $_{\rm p} = {\rm P} ({\rm T_f})^{\rm p}\bar{\rm c}$. The amplitude P (T_f) decreases with increasing T_f. A reas of high coverage have few pores and therefore P < 1.

Simulation results for the roughness $_t$ of the free surface (i.e. the standard deviation of t) can be compactly expressed as

$${}^{2}_{t}$$
 c [A (\underline{r}) + B (c)] (1)

(for general t_f and w_f we would of course expect that $t = t_f$ and $A = A (w_f T_f = t_f)$).

The functions A and B are shown in Fig. 5 for system size L = 100 and $c = 10^{\circ}$. They are independent of ber length as long as $l_{\rm f} = 5$. Equation (1) describes the coveragedriven cross-over from a 2D to 3D network structure. Hence, as coverage increases roughness is no longer a ected by the at substrate. This corresponds to B becoming sm aller than A. The decoupling is fast with still bers (A is large) because there are many pores in the network. The simulated roughness values can easily be decomposed according to Eq. (1) since the becomes constant (or A to 10) at large T_f.

The form of Eq. (1) arose from the observation that $_{\rm t}$ is controlled by high "peaks" and deep "valleys" of the surface. Hence the variance of t could be a sum of two terms especially since the "peaks" are dominant at low coverage or high ber exibility and the "valleys" at high coverage or low exibility. The exponential decay of roughness at a xed c (cf. A (T_f) in Fig. 5) then follows from the decrease in the depth of the "valleys". The planar ber network di ers from m any growth m odels [9] in that there is nothing that would play the role of surface tension, although uctuations of surface height are limited by T_f over the ber length. C learly, m aking T_f sm all does not give a sm ooth surface. In fact our m odel is sim ilar to the Vold m odel [19, 9]. The growth behavior at high coverage, including the e ects of system size and the naturally included overhangs, is beyond the scope of this study and will be presented elsewhere.

Sum marizing, we have presented a computer sinulation study of planar random ber networks. The results can be compared with experiments on disordered brous materials such as paper. At high coverage c the network is three-dimensional and its geometry is controlled by the scale-free combination of berwidth, thickness and exibility, ($w_f = t_f$)T_f, provided that $w_f = l_f$ 1 which usually holds bers. At low c the network is two-dimensional and its properties depend on the scale-free product of coverage and ber length, c l_f , provided that ($l_f = t_f$)T_f is large (4). Thus ber length is important only at low coverages. Our results connect the properties of realistic planar ber networks with those of ideal two-dimensional networks. In particular, if coverage is held constant then coordination number is linearly related to density for 0.6 but the slope depends slightly on c. Roughness of the free surface decreases exponentially with increasing T_f. Because of its simplicity our model could also be used to simulate other properties such as three-dimensional permeability and transverse compressibility.

This study was nancially supported by the Technology D evelopm ent C entre of F in land and by the A cadem y of F in land which is gratefully acknow ledged.
